CONTENTS.

[The dates of publication of the separate chapters are given in parentheses.]

	Page.
Fuel briquetting, by C. E. Lesher (Apr. 30, 1919)	1
Sand-lime brick, by Jefferson Middleton (June 10, 1919)	5
Gems and precious stones, by W. T. Schaller (July 16, 1919)	7
Prices of coal and coke, 1913–1918, by C. E. Lesher (Aug. 29, 1919)	15
Salt, bromine, and calcium chloride, by R. W. Stone (Aug. 16, 1919)	117
Fuller's earth, by Jefferson Middleton (Aug. 27, 1919)	135
Magnesite, by C. G. Yale and R. W. Stone (Sept. 16, 1919)	141
Sodium and sodium compounds, by R. C. Wells (Oct. 24, 1919)	159
Phosphate rock, by R. W. Stone (Oct. 4, 1919)	199
Graphite, by H. G. Ferguson (Oct. 20, 1919)	223
Slate, by G. F. Loughlin and A. T. Coons (Oct. 23, 1919)	267
Gypsum, by R. W. Stone (Nov. 6, 1919)	283
Sand and gravel, by R. W. Stone (Oct. 31, 1919)	299
Fluorspar and cryolite, by E. F. Burchard (Dec. 9, 1919)	317
Peat, by C. C. Osbon (Nov. 24, 1919)	331
Sulphur and pyrites, by P. S. Smith (Dec. 11, 1919)	357
Silica, by F. J. Katz (Dec. 4, 1919)	379
Potash, by W. B. Hicks (Mar. 31, 1920)	385
Asphalt, by C. C. Osbon (Mar. 31, 1920)	447
Mineral waters, by A. J. Ellis (Mar. 19, 1920)	495
Architectural concrete stone and concrete blocks in 1917 and 1918, by G. F. Loughlin (Mar. 16, 1920)	533
Strontium, by G. W. Stose (Mar. 30, 1920)	541
Asbestos, by J. S. Diller (Mar. 20, 1920)	545
Talc and soapstone, by J. S. Diller (Mar. 29, 1920)	557
Cement, by E. F. Burchard (Apr. 9, 1920)	565
Mica, by W. T. Schaller (May 24, 1920)	629
Coal—Part A, Production, by C. E. Lesher (May 28, 1920)	695
Lime, by G. F. Loughlin and Herbert Insley (June 7, 1920)	815
Clay-working industries, by Jefferson Middleton (July 14, 1920)	857
Feldspar, by L. M. Beach (June 28, 1920)	945
Barytes, by G. W. Stose (June 28, 1920)	951
Petroleum, by E. R. Lloyd (Sept. 20, 1920)	969
Abrasive materials, by F. J. Katz (Aug. 27, 1920)	1171
Stone, by G. F. Loughlin and A. T. Coons (Oct. 11, 1920)	1189
Coal—Part B, Distribution and consumption, by C. E. Lesher (Feb. 16, 1921)	1315
Natural gas, by E. G. Sievers (Nov. 10, 1920)	1393
Natural-gas gasoline, by E. G. Sievers (Nov. 10, 1920)	1403
Coke, by C. E. Lesher and F. G. Tryon (Apr. 18, 1921)	1439
Index	1529

		Page.
PLATE I.	Relative spot prices of coke, Connellsville district, Pa., by months, 1913–1918	
II.	Map showing location of the principal graphite deposits of the world	240
III.	Map of the United States showing distribution of peat deposits and approximate location of plants that produced peat in 1918	344
IV.	Map of the United States showing distribution of asphalt, petroleum, and related bitumens	468
V.	Map of the United States showing distribution of sources of mineral waters sold in 1918	496
VI.	Map of the United States showing distribution of active lime-producing districts in 1918	816
VII.	Fluctuations in value, quantity, and average price per ton of total lime and hydrated lime	816
VIII.	Average price per ton of lime for different uses, 1907–1918	816
IX.	Value of stone sold in the United States, 1880–1918	1194
X.	Value of Portland cement, structural clay products, and the more important stone products sold in the United States, 1892–1918	1194
XI.	Value of exterior building stone and of granite, marble, limestone, and sandstone sold for building in the United States, 1898–1918	1196
XII.	Value of stone products sold in the United States, 1898–1918, according to uses	1198
XIII.	Value of granite sold in the United States, 1898–1918, according to uses	1198
XIV.	Map showing relations between producing centers of granite and sandstone paving blocks and markets	1226
XV.	Value of limestone sold in the United States, 1898–1918, according to uses	1252
XVI.	Map showing origin and destination of bituminous coal traffic on the Great Lakes and the all-rail movement of bituminous coal to the Northwest from fields in Illinois and Indiana in 1918	1324
FIGURE 1.	Production of fuel briquets, 1907–1918, in the Eastern, Central, and Pacific Coast States and in the United States	1
2.	Production of bituminous coal in the United States, by months, 1913–1918	23
3.	Relative prices realized for all bituminous coal produced in the United States, by months, 1913–1918	30
4.	Relative spot prices for all bituminous coal produced in the United States, by months, 1913–1918	31
5.	Relative prices realized for bituminous coal produced in the Carterville and Franklin County district, Ill., by months, 1913–1918	32
6.	Relative spot prices, of bituminous coal produced in the Carterville and Franklin County district, Ill., by months, 1913–1918	33
7.	Relative prices realized for bituminous coal produced in the Mount Olive district, Ill., by months, 1913–1918	34
8.	Relative spot prices of bituminous coal produced in the Mount Olive district, Ill., by months, 1913–1918	35
9.	Relative prices realized for bituminous coal produced in the Springfield district, Ill., by months, 1913–1918	36
10.	Relative spot prices of bituminous coal produced in the Springfield district, Ill., by months, 1913–1918	37
11.	Relative prices realized for bituminous coal produced in the Standard district, Ill., by months, 1913–1918	38
12.	Relative spot prices of bituminous coal produced in the Standard district, Ill., by months, 1913–1918	39
13.	Relative prices realized for bituminous coal produced in the Clinton district, Ind., by months, 1913–1918	40

FIGURE 14. Relative spot prices of bituminous coal produced in the Clinton district, Ind., by months, 1913–1918 41
15. Relative prices realized for bituminous coal produced in the eastern Kentucky district, by months, 1913–1918 42
16. Relative spot prices of bituminous coal produced in the eastern Kentucky district, by months, 1913–1918 43
17. Relative prices realized for bituminous coal produced in the western Kentucky district, by months, 1913–1918 44
18. Relative spot prices of bituminous coal produced in the western Kentucky district, by months, 1913–1918 45
19. Relative prices realized for bituminous coal produced in the Georges Creek district, Md., by months, 1913–1918 46
20. Relative spot prices of bituminous coal produced in the Georges Creek district, Md., by months, 1913–1918 47
21. Relative prices realized for bituminous coal produced in the Hocking district, Ohio, by months, 1913–1918 48
22. Relative spot prices of bituminous coal produced in the Hocking district, Ohio, by months, 1913–1918 49
23. Relative prices realized for bituminous coal produced in the Pittsburg No. 8 district, Ohio, by months, 1913–1918 50
24. Relative spot prices of bituminous coal produced in the Pittsburgh No. 8 district, Ohio, by months, 1913–1918 51
25. Relative prices realized for bituminous coal produced in the Clearfield district, Pa., by months, 1913–1918 52
26. Relative spot prices of bituminous coal produced in the Clearfield district, Pa., by months, 1913–1918 53
27. Relative prices realized for bituminous coal produced in the Pittsburg district, Pa., by months, 1913–1918 54
28. Relative spot prices of bituminous coal produced in the Pittsburgh district, Pa., by months, 1913–1918 55
29. Relative prices realized for bituminous coal produced in Somerset and Cambria counties, Pa., by months, 1913–1918 56
30. Relative spot prices of bituminous coal produced in Somerset and Cambria counties, Pa., by months, 1913–1918 57
31. Relative prices realized for bituminous coal produced in the Kanawha district, W. Va., by months, 1913–1918 58
32. Relative spot prices of bituminous coal produced in the Kanawha district, W. Va., by months, 1913–1918 59
33. Relative prices realized for bituminous coal produced in the Pocahontas and New River fields, W. Va., by months, 1913–1918 60
34. Relative spot prices of bituminous coal produced in the Pocahontas and New River fields, W. Va., by months, 1913–1918 61
35. Relative spot prices of Alabama steam coal, by months, 1913–1918. 62
36. Shipments of Pennsylvania anthracite, by months, 1913–1918 90
37. Relative prices realized for Pennsylvania anthracite, all sizes, by months, 1913–1918 92
38. Relative spot prices of Pennsylvania anthracite, all sizes, by months, 1913–1918 93
39. Relative prices realized for Pennsylvania anthracite, stove size, by months, 1913–1918 94
40. Relative spot prices of Pennsylvania anthracite, stove size, by months, 1913–1918 95
41. Relative prices realized for Pennsylvania anthracite, egg size, by months, 1913–1918 96
42. Relative spot prices of Pennsylvania anthracite, egg size, by months, 1913–1918 97
43. Relative prices realized for Pennsylvania anthracite, chestnut size, by months, 1913–1918 98
44. Relative spot prices of Pennsylvania anthracite, chestnut size, by months, 1913–1918 99
45. Relative prices realized for Pennsylvania anthracite, pea size, by months, 1913–1918 100
46. Relative spot prices of Pennsylvania anthracite, pea size, by months, 1913–1918 101
47. Relative prices realized for Pennsylvania anthracite, steam sizes, by months, 1913–1918 102

MINERAL RESOURCES OF THE UNITED STATES, 1918—PART II.

FUEL BRIQUETTING.

By C. E. Lesher.

PRODUCTION.

The production of fuel briquets in 1918 was 477,235 net tons, valued at $3,212,793, an increase, compared with 1917, of 70,379 tons, or 17 per cent, in quantity and of $978,905, or nearly 44 per cent, in value. The production in 1918 was the highest recorded

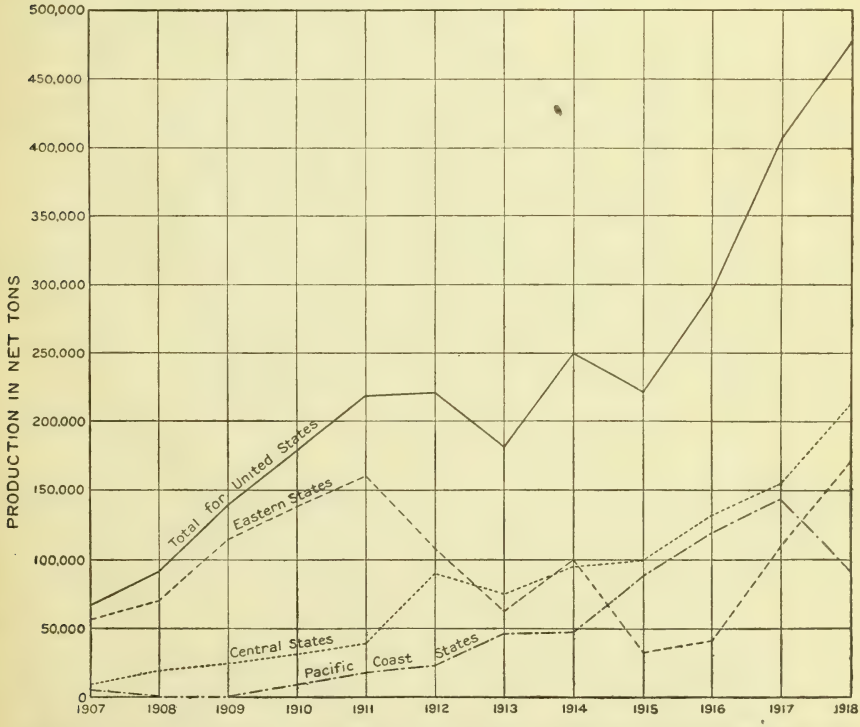

Figure 1.—Production of fuel briquets, 1907–1918, in the Eastern, Central, and Pacific Coast States and in the United States.

and represented the third successive year of material progress in the industry, being more than double the output in 1915. The progress of the industry in the 12 years 1907 to 1918, inclusive, is shown graphically in the accompanying diagram.

Fuel briquets produced in the United States in 1917 and 1918.

	1917			1918		
	Number of operating plants.	Quantity (net tons).	Value.	Number of operating plants.	Quantity (net tons).	Value.
Eastern States:						
New Jersey [a]				2		
Pennsylvania	4			3		
Virginia	1			1		
	5	108,632	$344,068	6	172,266	$728,017
Central States:						
Colorado [b]	1					
Missouri	1			1		
North Dakota [b]	1					
Wisconsin	2			2		
	5	155,140	1,056,051	3	213,030	1,741,769
Pacific Coast States:						
California	1			1		
Oregon	1			1		
Washington	1			1		
	3	143,084	833,769	3	91,939	743,007
	13	406,856	2,233,888	12	477,235	3,212,793

[a] No production in 1917. [b] No production in 1918.

Fuel briquets produced in the United States in 1907–1909 and 1911–1918, in net tons.

Year.	Quantity.	Value.	Year.	Quantity.	Value.
1907	66,524	$258,426	1914	250,635	$1,154,678
1908	90,358	323,057	1915	221,537	1,035,716
1909	139,661	452,697	1916	295,155	1,445,662
1911	218,443	808,721	1917	406,856	2,233,888
1912	220,064	952,261	1918	477,235	3,212,793
1913	181,859	1,007,327			

Raw fuels used in making briquets in 1917 and 1918, in net tons.

	1917	1918
Anthracite culm and fine sizes	137,659	209,690
Semianthracite	161,269	180,714
Semibituminous		
Bituminous slack		
Lignite and subbituminous coal	103,408	76,602
Oil-gas residue		
	402,336	467,006

In the Eastern States production increased 59 per cent and in the Central States 37 per cent, but in the Pacific Coast States production decreased 36 per cent.

The number of plants in operation in 1918 was one less than in 1917. Three of the plants that were operated in 1917 were idle in 1918—those of the Denver Coal By-products Co. (formerly the American Coal Reduction & By-products Co.) in Colorado, the Johnson Fuel Co. in North Dakota, and the American Briquet Co. in Pennsylvania. Two companies began operations at Trenton, N. J.,

in 1918—the Fuel Briquet Co. and the Trent Brick Co. The Belgian Coal Briquette Co., of New York City, and the Anthracite Briquet Co., of Sunbury, Pa., expect to begin operations in 1919.

RAW MATERIALS AND BINDERS.

Of the 12 plants in operation in 1918, 6 used anthracite as a raw material, 1 Arkansas semianthracite, 1 semibituminous slack, 1 anthracite culm and bituminous slack, 1 bituminous slack and subbituminous coal, and 2 oil-gas residue. Six plants used coal-tar pitch and asphaltic pitch for binders, 1 used sulphite pitch, 3 used vegetable binders or other special processes in manufacturing, and 2 used no binder.

SAND-LIME BRICK.[1]

By Jefferson Middleton.

The sand-lime brick industry in common with other building-material industries experienced a severe setback in 1918 by reason of the general conditions prevailing in that year. The decrease in output compared with 1917 was 89,147,000 brick, or nearly 48 per cent. The value decreased $536,401, or nearly 38 per cent. The principal causes of the decrease were the scarcity and high cost of materials and labor, congestion of transportation, and Government restrictions on the use of fuel and on general building. A further reason for the decrease in output in 1918 was possibly the adverse location of many sand-lime brick plants, which were far away from Government buildings that were under construction. With the resumption of general building, which is imminent, the sand-lime brick industry will no doubt share in the increasing demand for brick and show marked advance in 1919. The production in 1918 was the smallest recorded since 1905, and was 128,945,000 brick, or nearly 57 per cent, less than the output of 1916, the year of maximum production, and $590,144, or 40 per cent, less than the value for that year.

The number of operators (42) reporting marketed product in 1918 continued the decrease of previous years and was the smallest since 1903. The average value of sales per active operator in 1918 was $21,046, compared with $30,220 in 1917 and with $27,813 in 1916.

Eighteen States reported sand-lime brick in 1918, a decrease of one—Kentucky. Only one of these States, Louisiana, showed an increase in output; and three, Indiana, Louisiana, and Pennsylvania, increased in value of output. In 1918, as for many years, Michigan was the leading State in sales of sand-lime brick, reporting 23 per cent of the output and 22 per cent of the value. Minnesota ranked second in output but third in value; Pennsylvania was second in value and third in output; New York was fourth in value and sixth in output; Indiana was fourth in output and fifth in value; and Florida was fifth in output and eighth in value. The first five States rated by production reported about 60 per cent of the output and value in 1918.

The average price per thousand for common brick in 1918 was $8.94, compared with $7.54 in 1917 and $6.43 in 1916. For face brick the average price was $11.35, compared with $9.36 in 1917 and $9.64 in 1916.

[1] The statistical data in this report were prepared by Miss Katrine W. Cottrell, of the United States Geological Survey.

GEMS AND PRECIOUS STONES.

By Waldemar T. Schaller.[1]

PRODUCTION.

The production of gems and precious stones in the United States in 1918 was smaller than in any previous year since 1881, except in 1896. The value of the output in 1918 was only $106,523. The enlistment of many gem miners in the military service, the general scarcity of labor, and the poor market all had their effect in reducing the quantity and value of the precious stones produced.

Value of precious stones produced in the United States, 1913–1918.

	1913	1914	1915	1916	1917	1918

	319,454	124,651	170,431	217,793	131,012	106,523

a Small production included under "miscellaneous gems."

b Includes apatite, calamine, chlorastrolite, crocidolite, datolite, fossil coral, Iceland spar, kyanite, lapis lazuli, obsidian, peridot, phenacite, rutile, smithsonite, spodumene (kunzite), staurolite, thomsonite, titanite, and zircon.

c Includes chlorastrolite, datolite, epidote, fossil coral, hematite, kyanite, lazulite, rhodonite, rutile, sepiolite, serpentine, spodumene, staurolite, and vesuvianite.

d Includes andalusite, chlorastrolite, datolite, epidote, feldspar, fossil coral, hematite, Iceland spar, lapis lazuli, obsidian, peridot, phenacite, pyrite, rhodonite, rutile, sepiolite, smithsonite, spodumene, staurolite, thomsonite, willemite, and ziosite.

e Includes andalusite, calamine, chlorastrolite, datolite, epidote, feldspar, fluorite, Iceland spar, lapis lazuli, mariposite, meerschaum, obsidian, phenacite, pyrite, satin spar (gypsum), staurolite, thomsonite, willemite, and zoisite.

The value given in the table largely represents the value of the rough material; the value of the cut and polished gems is several times greater. The completeness and accuracy of the statistics of

[1] The tables giving statistics of the value of the gems and precious stones produced in the United States in 1918 were compiled by Miss Blanche H. Stoddard, of the United States Geological Survey.

production depend on the assistance rendered by the gem miners and dealers, and their help is greatly appreciated. The Geological Survey carries on a large correspondence concerning precious stones, and the information furnished by the individual producers enables the Survey to put intending purchasers of rough material directly in touch with them.

Corundum, quartz, tourmaline, and turquoise constituted 79 per cent of the total value of the precious stones produced in 1918.

Value of principal precious stones produced in the United States, 1911–1918.

Average for 1911–1918		58		11		8		8		85

[a] Includes ruby and sapphire.
[b] Includes all varieties of quartz, such as amethyst, rock crystal, chalcedony, agate, jasper, etc.

Reports of actual production were received from 57 persons and companies. A few of these persons are either lapidaries or collectors and not regular producers of precious stones. Thirty-eight distinct mineral species were mined; including all varieties as reported, a total of 75 named precious stones were produced. These came from 27 States (including Hawaii), 8 of which had a production valued at more than $1,000 each.

Value of precious stones produced in 1918, by States.

Montana	$47,753
Nevada	21,674
California	9,572
Arizona	9,206
Maine	7,132
Colorado	3,430
Arkansas and New Mexico	3,089
Other States [1]	4,667
	106,523

Montana continued to lead all the other States in the value of precious stones produced in 1918. The output consisted chiefly of corundum of the variety sapphire, which represented almost half of the total value of all precious stones produced in the United States in 1918. Other gem minerals produced in Montana were agate

[1] Florida, Hawaii, Idaho, Michigan, Minnesota, Nebraska, New Hampshire, New Jersey, New York, North Carolina, North Dakota, Oregon, Pennsylvania, South Dakota, Texas, Utah, Virginia, Washington, and Wyoming. Production of each State less than $1,000.

(chiefly moss agate), Iceland spar, garnet, and topaz; the last two amounted to only a few dollars in value.

Nevada ranked second in the output of precious stones, showing a greater value than for any other year since 1911. The most valuable gem mineral produced in Nevada was turquoise, followed by opal and variscite.

California was third in rank but had an unusually small output. The gem minerals mined were various forms of quartz (such as jasper, chalcedony, bloodstone, and chrysoprase), beryl, diamond, epidote, lapis lazuli, obsidian, rhodonite, spodumene, topaz, tourmaline, and vesuvianite. A three-quarter carat diamond was found in Cherokee Flat, Butte County, Calif.

Arizona had a production whose value was only a few hundred dollars less than that of California. The gem minerals produced include the copper-ore gems (azurite, malachite, azurmalachite, and chrysocolla), garnet, obsidian, peridot, opal, agate, jasper, and turquoise.

Maine produced beryl, garnet, amethyst and rock crystal, topaz, and tourmaline.

Colorado produced calamine, amazonstone, fluorite, garnet, hematite, opal, satin spar, phenacite, pyrite, various forms of quartz, topaz, and turquoise.

From Arkansas several hundred carats of diamonds were reported, including a canary-colored octahedron weighing 17.85 carats, a clear flat stone of 11 carats, and several smaller stones weighing several carats each.

In New York City garnet of gem quality was collected by Gilman S. Stanton and James G. Manchester in November, 1918, on Riverside Drive, north of West One hundred and sixty-fifth Street. The cut stones are deeper red than the spessartites found on the same ridge about half a mile farther north.[1] A number of stones have been cut, the largest about three-fourths of a carat in size. Chemical tests show that the garnet contains both iron and manganese, being intermediate in composition between almandite and spessartite.

In Hawaii an area of decomposed lava contains numerous yellowish-green crystals of peridot, which were cut in Honolulu into gems weighing as much as a carat and a half each. The crystals were separated from the sandy decomposed lava by sifting, and many also were brought to notice by the action of rain. Four workmen are said to have obtained 30,000 fragments of peridot in five days' work.

FOREIGN OCCURRENCES.

DIAMONDS IN SOUTH AFRICA.

A large blue-white diamond, weighing 388¼ carats [2] in its rough state, has been reported as found at the Jagersfontein mine, Orange River Colony, South Africa. Although small in comparison to the Cullinan diamond (3,052 carats), it will rank as one of the world's largest diamonds. The Jagersfontein mine in 1893 yielded the Excelsior, a diamond weighing 969½ carats in the rough. For comparison it may be stated that the largest cut stone obtained from the Cullinan weighs 516½ carats.

[1] U. S. Geol. Survey Mineral Resources, 1916, pt. 2, p. 894, 1918.

[2] Presumably "English carats." The weights of the older stones are given in English carats. One English carat weighs 205.304 milligrams.

A large diamond, free from flaws, was picked up by a native in September, 1917, on the Dutoitspan mine dump at Kimberley. The stone weighs 442¼ carats and is a record stone for this mine. Although slightly smaller than the large diamond of 503¼ carats discovered in the De Beers mine in 1896, the stone picked up recently is the most valuable diamond ever found at Kimberley in the mines of the De Beers Consolidated Mines Co.

It is said that there are not enough new diamonds in the world to supply the unprecedented increased demand from nearly all countries in the last few months. The shortage is due to the four and a half years of war, during which mining operations were completely suspended for a period of a year and a half and were resumed on a greatly reduced scale. The diamond dealers in the United States have in the meantime been replenishing their stocks from the accumulated surplus that had been mined prior to the war.

The competition which formerly existed in the world's diamond market has completely disappeared because of Germany's loss of German Southwest Africa, the output of which was large enough to be a factor in the market. The former German possession is now held by the British. With this competition eliminated, it is pointed out by leading American diamond dealers, 95 per cent of the world's production of diamonds will be under control of the De Beers Consolidated Mines Co. and its selling agents.

Holland and Belgium did most of the diamond cutting before the war, France and England cutting smaller quantities. The industry has been practically suspended in Belgium, has increased in Holland, and remains about the same in France and England.

It is estimated that about half of the mined diamonds of the world are owned in the United States and that their value exceeds a billion dollars.

AGATE AND AMETHYST IN URUGUAY.

Agates and amethysts are found in the Departments of Tacuarembo, Paysandu, Salto, and Artigas, in the northwestern part of Uruguay. Agate is abundant in many curious and beautiful forms and in a great variety of colors. Amethyst occurs in geodes, which are collected in the fields at a nominal cost, taken on mule-back or in carts to the nearest railway station, shipped from there in barrels to Salto, and thence by river boat to Montevideo. The finest amethysts, of a deep violet color, equal to the best European material, come from Artigas, near the Brazilian border.

Little exact information as to the output of amethyst is available. In 1909, which was a normal year, exports are estimated to have been between 13,000 and 15,000 pounds. Practically the entire output of rough amethyst and agate was formerly exported to Germany to be cut at Idar and Oberstein. The value of rough amethyst varies greatly according to purity and color, ranging from 10 centimos (10.34 cents) to 12 pesos ($12.41) per kilo (2.2 pounds), and exceptionally as high as 40 pesos ($41.36) per kilo has been paid. The output since 1914 has been very small and irregular, owing in part to the depletion of the supply of stones of good quality.

The Morgan Gem Hall of the American Museum of Natural History, New York City, has recently acquired a beautiful statuette, 8 inches high, of a woman dancing, carved out of an unusually perfect block of translucent natural sapphirine (blue quartz) from Uruguay.

IMPORTS AND EXPORTS.

The precious stones (excluding pearls) imported into the United States in 1918, as reported by the Bureau of Foreign and Domestic Commerce, Department of Commerce, were valued at $22,666,839. Pearls are omitted from the total value, as they are lustrous calcareous concretions with animal membrane between successive layers and are not a mineral but an animal product, being deposited in the shells of various mollusks. As pearls owe their beauty and value to the organic part of their composition, they do not come within the scope of this report. They are, however, among the most desired of gems, and their value is therefore given in a separate column in the table of imports.

Including pearls, the value of imported gems in 1918 was the lowest for the last 10 years except that in 1914.

Diamonds and other precious stones imported and entered for consumption in the United States, 1909–1918.

Year.	Diamonds.				Other stones not set.	Total, excluding pearls.	Pearls.

SOME INDUSTRIAL USES OF PRECIOUS STONES.

In the following paragraphs are given some industrial uses of minerals of gem quality. In addition to ornamentation, all gem minerals are of value as specimens for collections, for use in standardization (for example, fluorite and quartz as standards of densities and of refractive indices), and as sources of material for investigation, both industrial and scientific. These uses are therefore not always repeated under the different mineral names. Ornamentation itself covers a variety of utilization, such as for jewelry, knife handles, paper weights, and pipes (meerschaum).

Agate. Mechanical bearings and supports, scale bearings, balls for water meters.
Azurite. Ore of copper; pigment for paint.
Azurmalachite. Ore of copper.
Calcite. See Iceland spar.
Chromite. Ore of chromium.
Chrysocolla. Ore of copper.
Cobaltite. Ore of cobalt.
Corundum. See Sapphire.
Diamond. Cutting, grinding, engraving, boring, and polishing material; supports for bearings and pivots; dies for wire drawing; tips for phonograph needles.
Epidote. For coloring artificial slate and roofing material.
Fluorite. See Optical fluorite.
Franklinite. Ore of manganese and zinc.
Garnet. Abrasive; for watch jewels or jeweled bearings; as tared weights.
Garnierite. Ore of nickel.
Gypsum. Used in manufacture of artificial pearls—the so-called "Roman pearls."
Hematite. Ore of iron.
Iceland spar.—Iceland spar is a variety of calcite, clear and transparent and unusually free from imperfections and impurities. Transparent crystals or cleavage pieces of calcite of any appreciable size are very rare, and as Iceland has furnished almost all of such material used, the name Iceland spar has been given it.

Elongated cleavage rhombohedrons of Iceland spar are used in the manufacture of nicol prisms, which are an essential part of optical instruments requiring plane polarized light, as, for example, certain microscopes, dichroscopes, and saccharimeters. The material, on account of its simple chemical composition and purity, finds application in chemical standardization. Iceland spar is also used in the manufacture of some kinds of glass, and some of it is sold as mineral specimens.

Pieces of Iceland spar, either in single untwinned crystals or parts of such crystals, or in homogeneous untwinned cleavage rhombohedra, which are large enough to yield a rectangular prism at least 1 inch long and half an inch thick each way and which possess the properties described below, are suitable for optical purposes. The colorless material must be so clear and transparent that it is limpid and pellucid. It must not be partly opaque on account of numerous cracks or fractures, must not show any internal, iridescent, or rainbow colors due to

incipient cracks along fracture lines, nor any cleavage, nor twinning planes. Neither can there be any capillary or larger tubelike cavities, nor cavities or bubbles of any shape, nor inclusions, as isolated particles, veins, or clouds, composed of minute crystals of some other mineral or of any kind of foreign substance. The spar should not be discolored or stained by the presence of any clay, iron oxide, or other material. It should be noted that many of the inclusions and imperfections of Iceland spar are not always scattered irregularly through the mineral or even segregated in distinct masses, but frequently lie in a distinct but very thin plane which can hardly be seen if looked at on edge. In examining a piece of Iceland spar for defects the piece should therefore be turned in all directions while held to the light.

The material suitable for optical uses naturally brings the highest prices, as it has to be at least of the dimensions already given. Specimen material is generally of a larger size. The material used for standardization, chiefly chemical, need be of no special size, and the smaller pieces are as usable as the larger ones.

The optical variety of Iceland spar produced in the United States, sold, per pound, for $3 to $4 in 1914, about $8 in 1915, and as high as $20 in July, 1918. The specimen variety sells for considerably less, and material for standardization sells for from $1 to $2 a pound.

The following firms are buyers of Iceland spar suitable for optical use: Bausch & Lomb Optical Co., Purchasing Department, Rochester, N. Y.; Central Scientific Co., 460 Ohio Street east, Chicago, Ill.; Gilbert S. Dey, Superintendent Optical Department, Eastman Kodak Co., Rochester, N. Y.

The market for specimen spar is irregular, as the demand is usually very light. The best market will probably be found with some of the larger mineral dealers.

Standardization material may be sold to large dealers in general chemicals as well as to mineral dealers.

Although calcite is, next to quartz, the commonest mineral, the only locality outside of Iceland known to produce the variety Iceland spar in commercial quantity is in Montana, about 9 miles from Gray Cliff, Sweet Grass County, on the main line of the Northern Pacific Railway. The spar occurs in a nearly vertical fissure vein from 3 to 8 feet thick, which strikes northwest, traversing a gneissic rock for several miles.

Brief mention of the Montana occurrence of Iceland spar is made in the reports on the production of gems and precious stones in Mineral Resources for 1913 (p. 704) and 1914 (p. 335). C. L. Parsons, of the Bureau of Mines, has also described the occurrence and material in Science, vol. 47, No. 1221, pp. 508–509, May 24, 1918.

Jasper. See Agate.

Malachite. Ore of copper, pigment for paint.

Mariposite. Pigment for paint.

Meerschaum. Pipe bowls; cigar and cigarette holders.

Optical fluorite. Fluorite, commonly called fluorspar, is a common mineral but is very seldom found in pieces clear enough and large enough to be of special use in the manufacture of certain optical lenses and prisms. Fluorite of the requisite qualities, as described below, suitable for such use is known as "optical fluorite." Any deposit of fluorite may yield a small quantity of such material, but at present about the only localities known to produce it are southern Illinois; Meiringen, Switzerland; and Obira, Bungo, Japan. Optical fluorite is cut into lenses and placed between glass lenses. It forms the apochromatic objective for microscopes and similar optical instruments, the fluorite lens correcting the spherical and chromatic errors of the glass lens systems. This result is due to the low refractive power, weak color dispersion, and single refraction of fluorite. These apochromatic lenses represent the finest type of microscope objectives made. The use of such a fluorite lens greatly increases the value of a microscope and if optical fluorite were more abundant many more microscope objectives would be equipped with such lenses.

Optical fluorite is also used in the lenses of certain telescopes, in making prisms for spectrographs in ultra-violet work, and in other optical apparatus where transparency in the ultra-violet and infrared parts of the spectrum is necessary.

Optical fluorite must yield or contain pieces at least one-fourth of an inch in diameter, which must be clear and colorless and free from all defects. Defects consist of internal cracks or cleavage planes, bubbles, or inclusions of dirt or mineral matter. The presence of faintly developed or incipient cleavage planes or fracture surfaces usually may be determined, if not readily visible, by moistening the specimen with kerosene. The material must not show any anomalous double refraction. Absolutely water-clear material is of the highest value, but very faint tints of green, yellow, or purple do not render the material useless.

Fluorite suitable for optical use is valued at from $1 to $10 a pound, according to the size of the piece suitable for cutting as well as to its quality. The present yearly requirement is not large—perhaps several hundred pounds—but under proper conditions and with a dependable steady supply this requirement may be increased.

Possible buyers of optical fluorite are: Bausch & Lomb Optical Co., Rochester, N.Y.; Spencer Lens Co., Buffalo, N. Y.; Ward's Natural Science Establishment, Rochester, N. Y.; United States Bureau of Standards, Washington, D. C.

Suitable material has been obtained from several of the fluorite mines in Hardin County, Ill., and may also occur in the extension of this fluorite belt in western Kentucky. Although fluorite is found in many other States, practically none of them is known to contain any "optical fluorite."

Among publications dealing with optical fluorite are the following:

Pogue, J. E., Optical fluorite in southern Illinois: Separate from Bull. 38, Illinois State Geol. Survey, Urbana, Ill., 1918.

Burchard, E. F., Fluorspar and cryolite in 1917: U. S. Geol. Survey, Mineral Resources, 1918, pt. 2, pp. 301–302, 1918.

U. S. Bureau of Standards, Washington, D. C.: Circular letter dated May 8, 1918.

Quartz. See Rock crystal.

Rock crystal.—The perfectly clear and colorless variety of quartz is called rock crystal. It furnishes the material for certain special glasses and fused silica ware; and it is used in wedges for microscopic work, as spectographic prisms for special researches, and as mechanical bearings. A use in connection with certain sounding boxes has recently been developed.

Sepiolite. See Meerschaum.

Sapphire. The variety of gem corundum used for other purposes than jewelry is called sapphire, irrespective of its color. It is used for mechanical bearings and pivot supports, especially in watches and phonograph needles (mostly artificial sapphire).

Topaz. Abrasive.

Tourmaline. In the tourmaline tongs or in polarizing forceps, a very simple form of polariscope.

PRICES OF COAL AND COKE, 1913–1918.

By C. E. Lesher.

PREFATORY NOTE.

The following paper, which deals with the prices of domestic coal and coke from 1913 to 1918, inclusive, is one of 50 similar studies of war-time prices in different industries prepared by or at the request of the War Industries Board. The aim of these studies is both to make the price quotations gathered by various Government agencies available to men concerned with problems of business readjustment and also to provide a permanent record of the great revolution in prices that accompanied the World War.

This report is one of the products of the joint efforts of the United States Fuel Administration and the United States Geological Survey, which during the war combined their statistical work on coal and coke. It is published as a chapter in the history of the Fuel Administration and as a part of the annual report on the mineral resources of the United States by the Geological Survey for 1918; it is also combined with reports on other commodities in the history of prices published by the War Industries Board.

INTRODUCTION.

In order to throw as much light as possible upon the course of fluctuations in the prices of domestic coal and coke from 1913 to 1918, inclusive, a brief account of conditions prevailing in the coal industry during the period mentioned is given below, together with data regarding production and Government control and a discussion of the factors that exercised special influence upon the markets.

The price charts are drawn on a uniform scale.[1] As the inquiry centers about the effect of the war, the charts are made to show the movement of prices away from the pre-war level. This effect is produced by treating the average actual prices in the 12 months preceding the outbreak of war (July, 1913, to June, 1914, inclusive) as equal to 100 and throwing the actual prices in each month from January, 1913, to December, 1918, into the form of relative prices on that scale. For example, if the selling price of coal averaged $2 a ton in the 12 months before the war and if it fell to $1.80 in October, 1914, the relative price in that month would be 90; if the price rose to $4.60 in July, 1918, the relative price would be 230. On this plan, all the price charts are strictly comparable one with another.

For those who wish to know not merely the fluctuations of particular coals but also the general trend of prices in the bituminous and anthracite industries as a whole, "index numbers" are provided. As index numbers, simple averages of the prices of different coals would obviously have little value. Therefore, in making index numbers the price of each coal is "weighted" by multiplying the monthly

[1] The price charts in this report are uniform in scale with those in the reports on other commodities published by the War Industries Board.

prices from 1913 to 1918 by the quantity of that coal produced in 1917, which was selected as the weighting year both because the tables are intended to reflect war-time conditions and because when the bulletins were being written data for 1918 were unobtainable for many commodities other than coal.

An enumeration of the successive steps in making these index numbers will show how simple the figures are. First, for every coal included in the computation the quantity produced in the United States in 1917 was determined; this quantity represented the "weight." Second, the price of the coal in each month in the six-year period covered was multiplied by the "weight." Third, the products of the different coal prices by their respective "weights" were added up separately for each month. Finally, the monthly aggregates were turned into relatives on the pre-war base—that is, the average aggregates of July, 1913, to June, 1914, were made equal to 100, and all the monthly aggregates were computed to that scale.

Each grade of bituminous coal and each size of anthracite for which price charts are given in this report has been considered as a separate commodity. The prices of the several grades of bituminous coal have been combined into an index for bituminous coal as a whole, the result as shown including also all other bituminous coal and lignite produced in the United States, for which separate price quotations are not given. Likewise, the prices of anthracite have been combined to give one index for the industry as a whole.

It will be seen that the index numbers made on this plan for an industry are strictly comparable with the relative prices for particular commodities shown in the charts. By using these indexes readers can get a clear idea of average price fluctuations in a given branch of business and can compare fluctuations in one industry with those in others.[1]

The time allowed for the completion of this bulletin (two months) was not sufficient to permit as complete a study as was desired by the writer and as the subject deserves. But data regarding war prices appearing a full year after the armistice was signed would have possessed little practical value, however perfect they were as a historical record. The shortcomings of the bulletins as they stand are due largely to the effort to get them published in time to be of practical service to men facing the difficult problems of readjusting prices to a peace basis.

ACKNOWLEDGMENTS.

The writer is indebted to Mr. W. M. J. Lewis, of the Fuel Administration, for the compilation and preparation of all the price data and tables contained in the report. It is due to the energy and care exercised by Mr. Lewis that it has been possible to prepare the report in a little over the two months allotted.

[1] Besides the 50 pamphlets devoted to separate industries, the series published by the War Industries Board to which this bulletin belongs includes group studies of the prices of foods, fuels, clothing, metals, building materials, and chemicals. There is also a set of international comparisons of price fluctuations, a special record of Government control over prices during the war, and finally a general summary of the whole inquiry in which the methods employed are set forth more fully and in which also the leading results from all the bulletins are drawn together for comparison.

BITUMINOUS COAL.

GENERAL SUMMARY.

Selling price, cost of production, and quantity of output of bituminous coal bear interesting relations to one another. In the normal pre-war period represented in this study by the years 1913 to 1915 and the first half of 1916, the average price at which coal sold at the mines was very nearly parallel to and but slightly above the cost of production. The unmined reserves of bituminous coal are tremendous and widespread and yet within comparatively easy reach of railroads already built. Under the present wasteful methods of mining the cost of opening a mine is not great. Labor and machinery have been plentiful. Marketing has presented to the producer, big or little, no serious problems, for the middleman or jobber has furnished a convenient outlet for the output of mines whose operators had no direct connection with consumers. The railroads, the largest single group of coal consumers, have likewise offered an attractive and easily reached market.

In round numbers 80 per cent of the bituminous coal produced goes to the railroads, public utilities, and manufacturing industries, which, taken together, represent a market very little subject to seasonal change but subject to all the vicissitudes of business conditions—the prosperous and the dull times—that mark the ebb and flow of our industrial life. Of the remaining 20 per cent, 4 per cent represents exports—an item so small and local as to have no bearing on the total—and about 16 per cent is taken by domestic consumers, whose use of coal is of course seasonal.

Bituminous coal is not stored, except by the consumer, but moves direct from mine to user. Exceptions that do not affect the general validity of this statement are found in the stocks held in retail dealers' yards, in the not uncommon practice of holding coal in railroad cars—both small items—and in the use of storage docks at the head of the Great Lakes, where millions of tons for the northwestern trade are piled up during the season of summer navigation for use in the winter when the lakes are frozen over. The ability to get bituminous coal to the consumers, which involves not only the number and size of mines and the number of men but the number of railroads, engines, coal cars, switching yards, and sidetracks, must be ample to meet the maximum demand. And if the capacity of the mines and the railroads must be kept up to meet the periodic and temporary big demand for coal, it is evident that in periods of slack demand a part of this huge plant must lie idle. That this is what happens is shown by the statistics of running time. In 1913 there were employed in the production of bituminous coal 571,882 men, who worked an average of 232 days out of a possible 304 working days in the year; in 1914 583,506 men were employed an average of 195 days; in 1915 557,456 men averaged 203 days; and in 1916 561,102 men averaged 230 days. Idle time in these years, ranging from 72 days, or 24 per cent of the total of 304 days, in 1913 to 109 days, or 36 per cent, in 1914, was largely due to lack of business. Conditions in 1917 and the first nine months of 1918 were quite different from those in preceding years; demand generally exceeded supply and transportation was the principal factor limiting production.

An obvious result of having more mines than are needed at times is the curtailment of output at periods of slack demand and a lowering of prices in an effort to attract business. Cost of production has not always determined the lowest level of price, for ignorance of cost or desire to maintain the working organizations at the mines have often operated to maintain output beyond demand, at times with serious effect on the credit of the industry. For years much coal has been taken from the ground without adequate returns to the producers. The lure of cheap cost of production from thick beds—as in parts of West Virginia and Illinois—and of high prices in prosperous years and periods of coal shortage has attracted to the business of producing coal many men who, once in, have borne loss year after year in the hope of retrieving their losses later.

These conditions in the bituminous coal industry are significant and should be clearly recognized because they show why, in normal times, the price of bituminous coal is not subject to even moderately wide variations. The low levels are reached when those producers that are willing or able to reduce price have supplied the demand. Need for the commodity and not low price induces the purchase of coal. High levels of price are reached when, under the incentive of big profits, production is speeded up and capacity increased to a point where demand is satisfied.

Another and an important reason for fairly stable prices of coal is found in the fact that labor represents nearly 80 per cent of the total cost of production and that wages are pretty generally maintained through the unions. Coal miners' wages are fixed by agreements running from two to four years.

The general principles governing the prices in normal times thus set forth continued to operate through 1916 and until the middle of 1917, although in the later part of this period conditions were far from normal. A tremendous increase in demand, which began in the last quarter of 1916 and extended through 1918 until the armistice was declared in November, brought forth an increase in production to a point where the limit of railroad capacity was temporarily reached with the demand still unsatisfied. Because the demand could not be fully satisfied, prices in the fall of 1916 and in 1917 rose to almost unheard of figures, until first voluntary control and later Government control was exercised.

MARKETING METHODS.

Before describing the price data it is necessary for a proper understanding of the results presented to outline briefly the way in which coal is marketed and how the statistics of price fluctuations were compiled. Coal, like most other commodities, is sold either by contract or on the open market from day to day. Contracts are generally made (1) for a specified quantity to be delivered over a stated period and at an agreed rate per day, week, or month; (2) for a stated quantity per week or month for an indefinite period; (3) for the requirements of the consumer; or, (4) for the output of the mine. There are, of course, many variations to these four classes. Contracts specifying a definite period of time usually cover a year, and the most common period is from April 1 to March 31, the "coal year." Here again there are variations. Contracts are some-

times made to run for 5, 10, or even 20 years or more. In some fields and for some classes of business the period is not the standard coal year—for instance, railroad fuel contracts in northern West Virginia have usually been made for the period from July 1 to June 30, and the contract period in some of the Western States is September 1 to August 31. A contract period ending with March is logical because that date marks the end of the winter season, through which consumers desire the assurance of a coal supply afforded by a contract. In March and April stocks of coal left over from the previous year are often cleaned up while bargaining for the next year's supply is going on. In the central competitive field, comprising western Pennsylvania, Ohio, Illinois, and Indiana, the greatest of the unionized coal fields, wage agreements are dated from April 1.

Sales of coal on the open market, commonly called "free" or "spot" sales, represent an important part of the coal business. A substantial portion of the soft coal produced is sold through jobbers or wholesalers who do not physically handle the coal but simply buy and sell it. Producers may contract to sell their entire output or a definite quantity to a jobber or jobbers either for a stated price or for a fixed percentage of the ultimate selling price. So far as the producer is concerned such coal is under contract, but the jobber may sell the coal on the spot market or may in turn contract for its delivery to a consumer. Or the product of one or more mines may all be sold through a sales agency, usually on commission.

Although selling policy varies according to circumstances, producers and jobbers usually endeavor to place a substantial portion of their expected output under contract. The days a mine is idle not only mean no revenue but an increase in average cost of production. Contracts are the best assurance of continuous operation. The entire output of many mines is sold by contract to single consumers, such as railroads, public utilities, or large industrial establishments. The desire to make a contract for coal is strongest on the part of a producer when the market is falling and on the part of a buyer when the market is advancing.

There may be and usually are two prices for the same coal—the price at which the vendor will enter into a contract to deliver coal over a period of time and the price at which he will either sell a certain quantity at the time or accept an open order for delivery at the "market" price until further notice, essentially a spot sale. Spot prices may be higher or lower than contract prices, according to circumstances. They are, as a rule, lower in summer, because of slack demand, and higher in winter. Spot prices are often lowest in April, because in that month demand is lowest and buyers are concerned in negotiating for the lowest possible prices for the ensuing year's contracts.

The combination of all sales, both contract and spot, gives a figure of actual realization which represents the average of all transactions. Prices are the figures at which sales were made, without regard to the quantity sold. Average realization is obtained by dividing the total dollars obtained by the total tons sold and is therefore an average weighted price. Both prices and realization must be considered in a study of the history of prices such as is attempted in this report.

SOURCE, COMPLETENESS, AND METHOD OF COMPILATION OF PRICE DATA.

Current quotations from January 1, 1913, to September 1, 1917, on the several coals described separately in this report were taken from the weekly market reports of the trade paper, the Coal Age. Prices fixed by the President August 21, 1917, and subsequently modified by the Fuel Administrator, were used beginning with September, 1917. The mean of the high and low weekly quotations from the Coal Age were, where necessary, reduced to a basis of net tons and prices f. o. b. mines by deducting the freight rate in effect at the particular time. The weekly prices were then reduced to monthly prices by taking the simple average. A single quotation was then obtained for each coal for each month by averaging the quotations for prepared sizes, run of mine, and slack or screenings in accordance with the proportion of each size produced in each field in 1917. In this way more than 35,000 quotations were examined and reduced to 1,080 average monthly quotations—12 monthly averages each for six years for 15 bituminous coals. These are the "spot" prices given by years, quarters, and months for each of 15 coals in the tables. It is believed that the quotations from the Coal Age were fairly representative of the spot markets selected and that the method of combining the quotations for various coals at the several markets by sizes to a uniform run-of-mine basis gives a result that is as fair as can be shown within the limits of this report. Much interest would attach to a study of the current prices on different sizes of each coal, but the time available for preparation and the size of this report preclude an attempt to present that side of the subject.

The ideal set of figures would show for each coal, each month, three prices—the spot price, the contract price, and the average realization price, which would be a combination of the first two—all properly weighted in accordance with the quantity of coal delivered. Such figures are not available and would be impossible to obtain. Because so large a portion of the coal is delivered on contract, the spot quotations do not truly represent the price at which all bituminous coal is being marketed. The spot price is subject to greater and more frequent fluctuations than the contract price. A curve showing the average value in dollars and cents obtained from the sale of coal each month would, because of the steadying effect of contract sales, go neither so high nor so low as the curve of spot prices. An attempt has been made to set forth a set of figures showing average realization price, which are given both in tables and in diagrams and are described as "spot prices reduced to average realization base."

The method of arriving at the spot prices reduced to average realization base was as follows: The average realization price per ton for each calendar year was obtained from the reports on coal of the Geological Survey by dividing the total dollars received f. o. b. mines by the total number of tons of each coal. This figure is an average for 12 months and would be represented on the diagram by a straight line, with none of the monthly fluctuations that really took place. Furthermore, these annual averages are for calendar years, whereas the annual break in average realization more nearly corresponds to

the coal year beginning April 1. These annual average figures of realization were therefore arbitrarily moved forward three months, the figures for the calendar year 1914 being considered to apply to the 12 months beginning April 1, 1914, and ending March 31, 1915. Without regard to quantity of coal produced in any month, the spot prices for each coal year were reduced or raised proportionately, so that their arithmetic mean would equal the average realization price. On the assumption, arbitrarily made, that the average realization price represents the sale price of coal delivered on contract, that the modified spot prices represent the price on current sales, and that three-fourths of the coal was sold on contract and one-fourth on the spot market, a figure for each coal for each month was calculated that is three-fourths average realization price and one-fourth spot price reduced to average realization price.

From September, 1917, to December, 1918, the prices fixed by the Government were considered spot prices, and from April to December, 1918, the same prices were taken for the spot reduced to average realization, the actual realization for 1918 not being available. The figures are given in tables following those of spot prices.

It is believed that these figures represent the true condition of the market for coal more nearly than the spot prices. Whatever the objections to which this method of computation may be subject, it has the advantage of being based on a positive figure, the actual annual average return per ton of coal.

DISTRICTS.

Prices of bituminous coal are presented for 15 districts. The districts selected are those for which comparable quotations were available throughout the entire period of six years. There is no direct relation between these districts and the price districts established by the Fuel Administration. The market quotations carried in the Coal Age are quotations for standard grades of coal from what might be termed trade districts; cost of production was the determining factor in fixing the outlines of the price districts set up by the Fuel Administration. Central Pennsylvania is recognized by the Fuel Administration as one district, but prices are quoted separately for Clearfield coal and for Somerset and Cambria County smokeless coal. The Pocahontas and New River fields of West Virginia were, because of difference in cost of production, divided by the Fuel Administration into two price districts, whereas in normal times the coals from these two fields, of essentially the same quality, competed in the same markets without recognized difference in price. A number of districts treated separately in this report, as those in Illinois, had but one price, which was established by the Fuel Administration.

RELATIVE PRICES.

The diagrams show relative prices, not the actual or average prices described in the preceding paragraphs. This plan of presentation was adopted for this report and others of the series in order to make all price charts strictly comparable. To compare fluctuations in the prices of coal from the Standard field of Illinois, ranging from 84 cents to $2.87 a ton, with those in the prices of Pocahontas coal,

ranging from $1.09 to $5.34 a ton, the quotations for both are reduced to figures that represent the relation of the high and the low for each to a base price—that is, the average of prices for the 12 months preceding July, 1914. The base price for Standard coal was 91 cents and for Pocahontas $1.30. The base prices are taken as each equivalent to 100. The relative price of Standard coal at 84 cents as the spot price is 92 and for $2.87 as the spot price the relative price is 315. For Pocahontas coal the relative price corresponding to $1.09 spot is 84, and that corresponding to $5.34 is 410. In other words, Standard coal reached a spot price level that was 315 per cent of the average pre-war level, compared to 410 per cent for Pocahontas coal. The lowest level of relative price reached by Standard coal was 92 per cent of the pre-war level, compared to 84 per cent for Pocahontas coal.

In the same way the spot prices reduced to a realization base are converted to relative prices and shown on diagrams.

The price data for the several fields have been consolidated into a total for the United States, which shows the fluctuations for the bituminous industry as a whole through the six-year period. The series of spot prices and of spot prices reduced to realization base were reduced to totals by weighting the prices for each district in accordance with the number of tons produced in 1917—that is, each price was multiplied by the total production in 1917 of the coal represented by that price, the production for corresponding months totaled, and the sum divided by the total production, the result being a weighted average for the United States. These weighted average prices were then reduced to relative prices, as were also those for the several fields. The spot prices given in this report were considered representative of all coal produced east of Mississippi River except in Alabama and Michigan. For these fields and for the districts west of Mississippi River, representing together but 16 per cent of the total production of the country, the annual average realization prices were used in arriving at the averages for the United States in both computations. The error thus introduced is slight, for in those districts for which current quotations were not available, only a small portion of the product is sold on the spot market, and the portion so sold is an insignificant fraction of the total production of the United States.

PRICES.

The diagrams and tables on succeeding pages present the data on prices described above. Certain characteristics that are common to all the curves should first be noted. The most significant features are the abrupt rise in the last half of 1916 from a fairly uniform level in the preceding three and one-half years and the equally abrupt drop in the second half of 1917 after a period of abnormally high prices in the first six months of 1917. The spot market prices, as well as the contract prices, reflect the same tendencies, although not in the same degree. The rise in 1916 followed an increase in demand that the increase in production was unable to satisfy. The drop beginning with July, 1917, was the result of Government control of prices. Discussion of the prices must necessarily be divided at the point where the law of supply and demand was replaced by edict of Government or other arbitrary action.

In the period prior to July, 1917, the general trend of prices was downward from January, 1913, to July, 1915. In January, 1913, prices in all districts were good and, in the eastern fields, somewhat abnormal. The market in the eastern fields particularly for coal for coastwise business, was better than for more than a year. By the end of January, 1913, the demand declined with unseasonably warm weather, and all districts, except Indiana, recorded a steady drop in the spot price through February and March and, in most of the fields, through April, 1913. The low point for the year was reached in June and July with prices, particularly in the Ohio, West Virginia, and Kentucky fields, rising to a peak in October and November. The

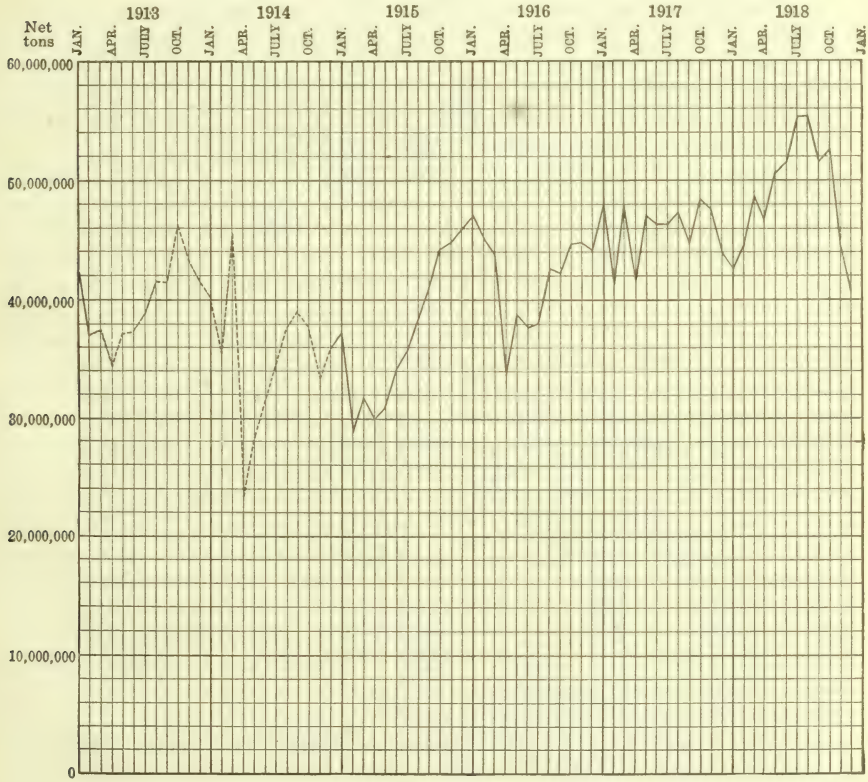

FIGURE 2.—Production of bituminous coal in the United States, by months, 1913–1918.

high point in both price and production for the winter of 1913–14 was reached in October, several months earlier than usual. The price curve for the United States in 1913 (fig. 4, p. 31) follows closely the curve of production (fig. 2). The higher prices in the last half of the year brought forth increased production. It is significant that the peak of production in October, 1913, was nearly as high as in January, 1916, and but little below the maximum reached in 1917, and also that in September and October, 1913, reports of car and labor shortage were currently made. It is evident that, had demand been sustained through the winter of 1913–14, the limitations of car and labor supply would have caused a serious shortage of fuel and a period of high prices

comparable at least to the winter of 1915–16. The industrial depression of 1914 really began in November, 1913, and caused a falling off in demand that relieved the situation. A large production in March, 1914, was followed in April by the lowest production recorded in the six years under discussion with no marked change in prices. Although demand and production gained through the summer and reached a maximum in September, prices generally continued downward. The only districts that exhibited any marked activity at the end of 1914 were Pittsburgh, Pa., and No. 8, Ohio.

From the low point in April, 1915, production began an increase that was sustained for nine months, or until January, 1916. Spot prices however, did not begin to advance until after the middle of the year, and, except for central Pennsylvania coal and to a less extent for Pittsburgh coal, the advance which reached a climax in January, 1917, was not exceptional. The flurry in prices for Clearfield, Somerset, and Cambria County coals in the winter of 1915–16 was the first evidence of the impending shortage that became so notable a feature from October, 1916, to the end of the war.

The orders of the Allies for war materials were at first largely placed in New England, and the speeding up of industries in that section made the demand for coal from the tributary all-rail fields of eastern Pennsylvania so insistent that spot prices soared to more than double those prevailing only a few months previously. This peak in the price curve was followed by a recession in the spring and early summer of 1916. Beginning in July in many districts and by August in all, prices started upward in response to a demand whose insistence was not appreciated at the time. With a suddenness and to an extent probably unequaled in the history of the bituminous-coal industry, spot prices rose nearly 200 per cent in the short period of six months. In Ohio and Pennsylvania the increase was the greatest, the highest spot price recorded being more than 300 per cent above the pre-war level. The smokeless coals of West Virginia and the high-grade coal from the Georges Creek district of Maryland showed the next highest rise in price. Prices for current delivery remained at the high level during the first six months of 1917 in the eastern fields, but declined in Indiana and in Illinois with the exception of the Franklin County district. In all districts the price in April for free coal represented a low point, a condition usual in every year, whether prices are high or low.

Public discontent with the continued high prices was manifested strongly in June. Notwithstanding the fact that it was the bidding of the consumers against one another that brought about the high prices to an extent equal to if not greater than the setting of the prices by the producer, the producer of coal was held to be responsible for the condition. The Committee on Coal Production of the Council of National Defense, organized in May, 1917, with F. S. Peabody as chairman, called a meeting of representative coal operators from all fields at Washington on June 26 to consider the situation. At the meeting it was made evident that the producers of bituminous coal were willing voluntarily and in concert to reduce prices, but were in fear of condemnation by the Department of Justice for such reduction as combination in restraint of trade. This cause for hesitation was overcome by the action of the Secretary of the

Interior, the Federal Trade Commission, and the Committee on Coal Production, as representatives of the Government, in standing sponsors for the action of the coal producers. On June 28, 1917, a scale of spot prices was agreed upon, to be effective July 1. A letter from Secretary Lane to Mr. Peabody urging the action by the coal operators, the resolutions passed by the convention, and the statement of agreed prices are given here because they so well express the results of this historic gathering of coal producers.

Letter of Secretary Lane to Mr. F. S. Peabody:

DEPARTMENT OF THE INTERIOR,
OFFICE OF THE SECRETARY,
Washington, June 28, 1917.

DEAR MR. PEABODY: I feel that the present extremely high prices on coal require immediate action by the coal operators and therefore would urge upon you that they should be reduced at once and maximum prices fixed which would apply to sales on and after July 1, 1917, and continue until such time as the investigation which you propose into costs and conditions shall warrant a reduction or increase. These prices should not be used to affect present contracts or apply to export or foreign trade. In other words, the people of the United States should have, as I urged upon the operators the other day, immediate relief and knowledge of their disposition to make a reasonable price irrespective of the possibilities of obtaining higher prices. This would be regarded by the people as meeting the situation promptly and wisely if the prices materially cut those which exist.

Cordially, yours,

FRANKLIN K. LANE.

Mr. F. S. PEABODY,
Chairman, Committee on Coal Production,
Council of National Defense.

Resolutions adopted by the convention of coal operators at Washington, D. C., June 28, 1917:

Whereas under the act of Congress approved August 29, 1916, providing that a Council of National Defense be established "for the cooperation of the industries and resources for the national security and welfare, to consist of the Secretary of War, the Secretary of the Navy, the Secretary of the Interior, the Secretary of Agriculture, the Secretary of Commerce, and the Secretary of Labor," authority is given to the council to organize subordinate bodies for its assistance and cooperation, and

Whereas pursuant to this authority the Council of National Defense has appointed Mr. Francis S. Peabody, chairman of and with authority to appoint a Committee on Coal Production, representative of the coal-producing districts of the United States, and

Whereas a great national emergency now exists in the fuel supply of the Nation, and as the coal operators and miners of the United States desire to cooperate as closely as possible with the Government, and as the Department of the Interior, the Federal Trade Commission, and the Committee on Coal Production have given close and intelligent study to the necessities now existing: Therefore be it

Resolved, That it is the sense of this meeting that a committee of seven for each coal-producing State and an additional committee of seven appointed by the representatives of the anthracite industry be appointed by the representatives of each State now attending this convention, to confer with the Secretary of the Interior, the Federal Trade Commission, and the Committee on Coal Production of the Council of National Defense, to the end that production be stimulated and plans be perfected to provide adequate means of distribution, and, further, that these committees report forthwith to the Secretary of the Interior, the Federal Trade Commission, and the Committee on Coal Production of the Council of National Defense costs of and conditions surrounding the production and distribution of coal in each district, and that these committees are authorized, in their discretion, to give assent to such maximum prices for coal f. o. b. cars at mines in the various districts as may be named by the Secretary of the Interior, the Federal Trade Commission, and the Committee on Coal Production of the Council of National Defense.

* * * * * * *

This convention by resolution heretofore adopted having requested the Secretary of the Interior, the Federal Trade Commission, and the Committee on Coal Production to fix a fair and reasonable price at which the several operators in the several coal districts of the United States shall sell coal, do hereby further authorize said Government representatives, so named in said resolution, to forthwith issue a statement fixing a tentative maximum price which, in their judgment, is fair and reasonable as applied to the several coal districts, at which coal shall be sold from and after the first day of July next and until the accurate costs have been ascertained and a fair and reasonable price based thereon fixed by said Government agencies designated under said resolution: To this end therefore be it

Resolved, That the several States, here represented, do present to the chairman of this this convention a suggestion for use by said agencies in fixing the price which the several interests here represented feel should be the fair and reasonable price to be so tentatively fixed by the said agencies.

The following memorandum of the proceedings was given to the press the night of June 28, 1917:

DEPARTMENT OF THE INTERIOR,
OFFICE OF THE SECRETARY.

As a result of the conference between the mine operators, the Secretary of the Interior, Federal Trade Commissioner Fort, Chairman Peabody, and the Committee on Coal Production of the Council of National Defense, the following reductions were made to go into effect July 1 next in the prices of coal. These prices are maximum prices per ton of 2,000 pounds aboard the cars at mine, pending further investigation. These prices do not affect in any way contracts in existence or sales of coal for foreign or export trade.

The operators tendered to the Government a reduction from these reduced prices of 50 cents per ton for coal that the Government may need.

No action was taken upon anthracite prices because of the fact that these prices had already been acted upon by the Federal Trade Commission.

Twenty-five cents per ton net was fixed as the maximum price for coal jobbers' commission, with only one commission, no matter how many jobbers' hands the coal may pass through.

On account of an inadequate representation of operators west of the Mississippi River, no maximum prices were fixed for coal from those districts. A supplementary statement will be issued within a few days covering prices on coal produced in those districts.

The action taken at this conference brings about the following results:

Present prices on bituminous coal mined in Pennsylvania have ranged from $4.75 to $6. Under the ruling the price is reduced to $3 for mine run and $3.50 for domestic lump, egg, and nut.

The present range of prices in West Virginia is from $4.50 to $6; price reduced to $3 for mine run and $3.50 for domestic lump, egg, and nut.

The range of prices for Ohio coal has been from $4.50 to $5; prices reduced to: No. 8 district, the thick-vein Hocking and Cambridge districts, $3 for mine run and $3.50 for domestic lump, egg, and nut; thin-vein Hocking, Pomeroy, Crooksville, Coshocton, Columbiana County, Tuscarawas County, Amsterdam-Bergholz district, $3.25 for mine run and $3.50 for domestic lump, egg, and nut; the Massillon and Palmyra districts and Jackson County, $3.50 for all grades of coal.

The prevailing prices in Alabama have been from $5.50 to $5.75; prices reduced to: Cahaba and Black Creek, $4; Pratt, Jaeger, and Corona, $3.50; Big Seam, $3 for all grades.

The prevailing prices for coal mined in Maryland have been from $5.75 to $6; reduced prices will be $3 for mine run and $3.50 for domestic lump, egg, and nut.

The prevailing prices on coal mined in Virginia have been $4.50 to $5; reduced price, $3 for mine run and $3.50 for lump, egg, and nut.

The prevailing prices on coal mined in Kentucky have been from $4 to $4.50; reduced price, $3 for mine run and $3.50 for the domestic sizes.

The prevailing prices on coal mined in Illinois and Indiana have been from $3.50 to $4; reduced price, $2.75 for mine run and steam sizes and $3.50 for screened domestic sizes.

The prevailing prices on coal mined in Tennessee have been from $4.50 to $5; reduced price, $3.50 for all sizes.

Whether the reduction in prices thus effected by the voluntary action of the producers would have satisfied the public and met the needs of the situation will never be known, for no sooner were the

results announced than the Secretary of War, in his capacity as chairman of the Council of National Defense, publicly repudiated the action of the Committee on Coal Production, stating that the prices agreed upon were unwarrantably high.

It is not necessary to pass judgment here on the reasonableness of the Peabody prices. That they were higher than necessary to return the cost of production and a moderately fair profit to the producers has been clearly shown by the subsequent investigation of the committee of engineers of the Fuel Administration. The important point is that the Peabody prices were substantially below those prevailing at the time, that they were from their inception understood to be a temporary stop-gap pending a careful determination of more exact and proper prices, and that they were the first and practically the only prices established by an industry as a whole that represented a reduction for the benefit of the entire public in the history of this war.

The Peabody prices for spot sales were generally observed during July and, except in eastern Pennsylvania and the smokeless-coal districts of West Virginia, in August also until August 21, when the prices were fixed by the President under the authority of the Lever Act. The Peabody prices did not apply to coal sold for export and, as a result, Canadian consumers were able to outbid consumers in the United States. New England and Canada depend upon the fields in central Pennsylvania for their supply by railroad routes. Under these circumstances New England consumers were unable, in July, to obtain satisfactory deliveries of bituminous coal, and in August they induced operators in central Pennsylvania to break away from the Peabody prices. It is thus to be recorded that, although the Peabody prices were claimed to be exorbitant, the only important divergence from those prices resulted from the action of consumers and was an increase.

Government control of the coal industry was assured by the passage by the Congress of the food and fuel control act, generally known as the Lever Act, approved by the President August 10, 1917 (Public—No. 41, 65th Cong.). Acting under the authority of this act the President, on August 21, 1917, announced the following scale of prices for bituminous coal and, on August 23, announced the appointment of H. A. Garfield as United States Fuel Administrator to administer these prices and the provisions of the Lever Act relating to fuel.

THE WHITE HOUSE,
WASHINGTON, *August 21, 1917.*

The following scale of prices is prescribed for bituminous coal at the mine in the several coal-producing districts. It is provisional only. It is subject to reconsideration when the whole method of administering the fuel supplies of the country shall have been satisfactorily organized and put into operation. Subsequent measures will have as their object a fair and equitable control of the distribution of the supply and of the prices not only at the mines but also in the hands of the middlemen and the retailers.

The prices provisionally fixed here are fixed by my authority under the provisions of the recent act of Congress regarding administration of the food supply of the country, which also conferred upon the Executive control of the fuel supply. They are based upon the actual cost of production and are deemed to be not only fair and just but liberal as well. Under them the industry should nowhere lack stimulation.

WOODROW WILSON.

Prices of bituminous coal fixed by Executive order of August 21, 1917.

	Run of mine.	Prepared sizes.	Slack or screenings.
Pennsylvania	$2.00	$2.25	$1.75
Maryland	2.00	2.25	1.75
West Virginia	2.00	2.25	1.75
West Virginia (New River)	2.15	2.40	1.90
Virginia	2.00	2.25	1.75
Ohio (thick vein)	2.00	2.25	1.75
Ohio (thin vein)	2.35	2.60	2.10
Kentucky	1.95	2.20	1.70
Kentucky (Jellico)	2.40	2.65	2.15
Alabama (big seam)	1.90	2.15	1.65
Alabama (Pratt, Jaeger, and Corona)	2.15	2.40	1.90
Alabama (Cahaba and Black Creek)	2.40	2.65	2.15
Tennessee (eastern)	2.30	2.55	2.05
Tennessee (Jellico)	2.40	2.65	2.15
Indiana	1.95	2.20	1.70
Illinois	1.95	2.20	1.70
Illinois (third vein)	2.40	2.65	2.15
Arkansas	2.65	2.90	2.40
Iowa	2.70	2.95	2.45
Kansas	2.55	2.80	2.30
Missouri	2.70	2.95	2.45
Oklahoma	3.05	3.30	2.80
Texas	2.65	2.90	2.40
Colorado	2.45	2.70	2.20
Montana	2.70	2.95	2.45
New Mexico	2.40	2.65	2.15
Wyoming	2.50	2.75	2.25
Utah	2.60	2.85	2.35
Washington	3.25	3.50	3.00

NOTE.—Prices are f. o. b. mine, basis of 2,000 pounds.

The prices fixed by the President on August 21 were generally about as much below the Peabody prices of July 1 as the Peabody prices were below the spot prices prevailing in June. The opinion was more or less generally expressed by coal producers at the time that for many fields the prices fixed by the President upon the advice of the Federal Trade Commission were too low to stimulate production to supply the needs of the country, although it was granted that a considerable portion of the possible output could be produced at a fair profit under those prices. That this view was correct has been shown by the numerous advances in base price authorized by the Fuel Administrator after full investigation of the cost of production. Some of the more important revisions of the original prices, made as a result of the investigation of the engineers' committee of the Fuel Administration, were those in eastern Kentucky; Kanawha, W. Va.; Georges Creek, Md.; central Pennsylvania; and Hocking, Ohio.

There were two subsequent orders that had a general effect on prices of bituminous coal. On October 27, 1917, the President amended prices generally by adding 45 cents a net ton to the mine price to cover the additional labor cost resulting from the wage advance agreed upon October 6. On May 25, 1918, the Fuel Administrator reduced the price at the mine of all bituminous coal 10 cents a net ton. This reduction was made because of the estimated general leveling and lowering of cost of production accomplished by the elimination of all preferments in car supply, which was brought about by the President acting through the United States Railroad Administration.

Spot prices are only partial evidence of the trend of prices; they are indicative of changing conditions in supply and demand, condi-

tions which change from day to day and from week to week. Transactions representing sales of coal for periods of a year or more at stable contract prices affect a much larger portion of the output than sales at spot prices. The average prices realized from the sale of all the coal produced do not rise as high or drop as low as the spot prices during the same periods. This is shown in the tables of prices and by the diagrams of relative prices, based on average realization prices and on spot prices. In addition to the relatively lesser variations in average prices realized compared with spot prices, other important differences are the lag in either the rise or the fall of average prices realized compared with spot prices; the usual decline in spot prices in April in periods of rising prices as against increases in average realization prices the same month; and the relatively higher level of the Government prices at the end of 1918 compared with the average pre-war realization prices and with average spot prices in the pre-war period. This was true in all districts for which data are separately presented except two, the Standard and Springfield districts of Illinois. The only significance that attaches to the two districts excepted is that the spot price level in the 12 months preceding the war (the base period) was lower than the average realization price. For one district only of those separately examined, the Carterville and Franklin district of Illinois, the averages of spot prices and of realization prices were identical for the base period.

Comparison of the diagrams of relative prices based on average realization and on spot prices shows also two groups. One group comprises western Kentucky, Illinois, and Indiana, in which the relative increases in the President's prices of August 21, 1917, were greater when compared with the pre-war spot prices than when compared with the pre-war average realization—that is, the first prices fixed, in August, 1917, in those districts were not substantially below the prices prevailing then on all sales. In the other group, mainly the eastern fields, relatively greater decreases were represented in the original prices fixed by the President, and it is to be noted that in this group were allowed subsequently practically the only important revisions upward as the result of investigations of cost of production.

It is perhaps of most importance to note that, although the prices fixed by the Government were substantially below the high levels prevailing in the winter of 1916–17, those finally arrived at in the last half of 1918 were in turn substantially above the average realized on all coal produced in 1916 or 1917, although until the actual amount in dollars realized from the marketing of the 1918 output is known and those figures are substituted for the Government prices in the accompanying tables and diagrams, the actual difference can not be accurately stated. This is true because in this report the prices fixed by the Government have been used from April to December, 1918, both as spot and average realization, whereas the number of contracts extending through this period at prices below the Government maximum may and probably will reduce the average realization price as given. It is not believed, however, that this difference will be great, and the inference to be drawn, from a consideration of all the data presented is that the years 1917 and 1918 represent, for the bituminous coal industry in general, prosperous years.

It would be interesting to show in this report the relative changes in cost of production for comparison with the changes in prices, but the time allotted to the preparation of the report is so short as to preclude such an undertaking. Complete data on which to base a comparison of the cost of mining of bituminous coal through this period are lacking, but much light would be thrown on the subject by comparison of wages (labor constitutes 75 per cent of the cost of production) and of the cost of some of the principal supplies and machinery used in mining. It is believed that the cost of mining did not advance in proportion to the selling prices; but it is not to be inferred from this that prices in the later years and the Government prices were too high, but rather that in the earlier years of the period under consideration the average margin of profit was very small and that the coal produced was derived largely from the lower-cost operations. To bring forth the greatly needed additional output in the last three years it was essential that many of the higher-cost mines be operated, and to do this a higher average price was necessary.

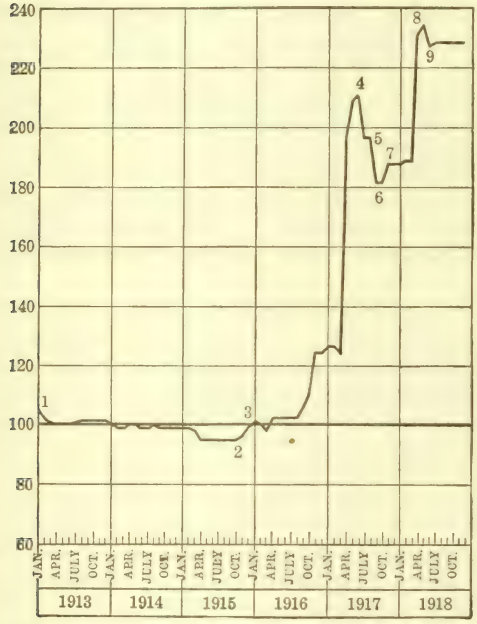

FIGURE 3.—Relative prices realized for all bituminous coal produced in the United States, by months, 1913–1918.

Another feature of the spot prices presented in this report to which no reference has been made thus far concerns the jobber's or middleman's margin. It is assumed that the prices quoted from the Coal Age, on which the tabulation of spot prices has been based, include generally the jobber's margin. For instance, the prices of Pocahontas and New River coal f. o. b. mines are quoted on the Boston market by Boston wholesale houses and must include such wholesaler's margin. The Government prices used in place of quotations in 1917 and 1918 are f. o. b. mines but do not include the jobber's margin or, as finally defined, the purchasing agent's commission.

DIAGRAMS OF RELATIVE PRICES OF BITUMINOUS COAL, 1913–1918.

TOTAL OUTPUT.

The diagrams herewith (figs. 3–35) show the relative prices per ton of 2,000 pounds of all bituminous coal produced in the United States, by months, from 1913 to 1918, inclusive. The numbers preceding the notes in small type refer to corresponding numbers on the diagrams.

Figure 4 shows the relative spot prices in this period compared with the average spot prices in the 12 months preceding the war, July, 1913, to June, 1914. Figure 3 shows the relative range in estimated average

realization prices (see p. 30) of all sizes and includes both spot and contract transactions. The spot prices are taken from the market quotations of the Coal Age and the average realization prices from annual reports of operators compiled by the United States Geological Survey. Tables of actual prices and of the computed relative prices from which these diagrams were drawn are given on pages 64–87.

Production, 1917, 551,790,000 net tons. Average spot price, pre-war period, $1.27; average realized price, $1.17.

FIGURE 4.—Relative spot prices of all bituminous coal produced in the United States, by months, 1913–1918.

1, 2. The downward trend of the price of bituminous coal in 1913, 1914, and 1915, is shown by both the spot prices and the average prices realized. From a general average spot price of $1.47 in January, 1913 (1), prices declined to $1.14 in July, 1915 (2).

3. The strength of the demand in the winter of 1915–16, particularly manifested in the Eastern States, is indicated by the rise in the general average spot price to $1.54 (3).

4. The highest point reached by the general average spot price was $3.77 in June, 1917 (4).

5. The amount of reduction effected by the Peabody prices is well illustrated by the drop in the curves from (4) to (5).

6. Likewise, the further decrease in the general level of prices brought about by the President's price of August 21, 1917, is shown by the drop in the curves from (5) to (6).

7. The general effect on prices of bituminous coal of the wage advance in November, 1917, is indicated by the rise from (6) to (7).

8. Advances in price in various fields authorized by the Fuel Administrator as the result of investigations of the cost of mining raised the general level gradually to a maximum under Government control in May, 1918 (8).

9. The general reduction in price of 10 cents a ton on all bituminous coal ordered May 25, 1918, is reflected in the curves at (9).

CARTERVILLE AND FRANKLIN COUNTY DISTRICT, ILL.

Figure 6 shows the relative spot prices in this period compared with the average spot prices in the 12 months preceding the war, July, 1913, to June, 1914. Figure 5 shows the relative range in estimated average realization prices from all sales and includes both spot and contract transactions. The spot prices are taken from the St. Louis market quotations of the Coal Age and the average realization prices from annual reports of operators compiled by the Geological Survey. Tables of actual prices and of the computed relative prices from which these diagrams were drawn are given on pages 64–66.

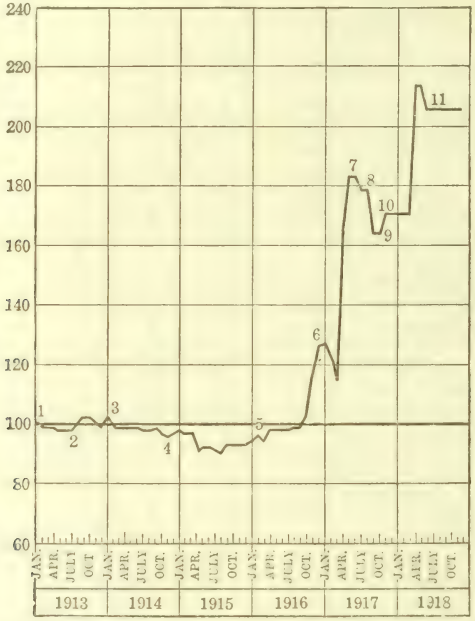

FIGURE 5.—Relative prices realized for bituminous coal produced in the Carterville and Franklin County district, Ill., by months, 1913–1918.

Production, 1917, 28,000,000 net tons. Average spot price, pre-war period, $1.16; average realized price $1.16.

1–5. The average monthly quotations for Carterville and Franklin County coal on the St. Louis market in the period beginning with 1913 to the first half of 1915 ranged from $1.19 in January, 1913 (1), to a low point in June, 1913, of $1.08 (2), and to $1 in November, 1914 (4), and the high price in January, 1914, of $1.28 (3), and in February, 1916, of $1.25 (5).

6. The maximum average monthly quotation for the six-year period covered by this report was for January, 1917, $3.30 (6).

7. Prevailing quotations in May and June, 1917, when the Peabody prices were established, were around $3.19 (7).

8. The prices in July and August, during which the Peabody agreement was in effect, are indicated at (8).

9. The prices established by the President at the end of August, 1917, are indicated at (9).

10. The increase of 45 cents per ton allowed the operators to cover the advance in mine wages authorized in November, 1917, are indicated at (10).

11. The general reduction of 10 cents per ton ordered by the Fuel Administrator on May 25, 1918, is indicated at (11).

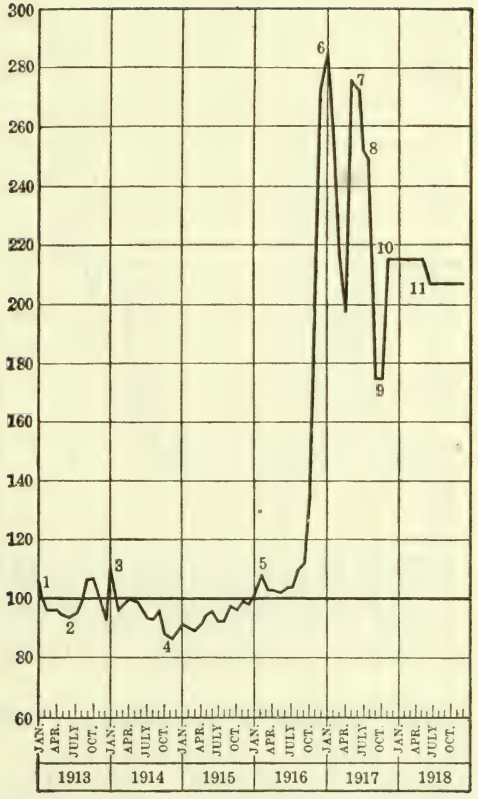

FIGURE 6.—Relative spot prices of bituminous coal produced in the Carterville and Franklin County district, Ill., by months, 1913-1918.

137536°—M R 1918—PT 2——3

MOUNT OLIVE DISTRICT, ILL.

Figure 8 shows the relative spot prices in this period compared with the average spot prices in the 12 months preceding the war, July, 1913, to June, 1914. Figure 7 shows the relative range in estimated average realization prices from all sales and includes both spot and contract transactions. The spot prices are taken from the St. Louis market quotations of the Coal Age and the average realization prices from annual reports of operators compiled by the Geological Survey. Tables of actual prices and of the computed relative prices from which these diagrams were drawn are given on pages 64–66.

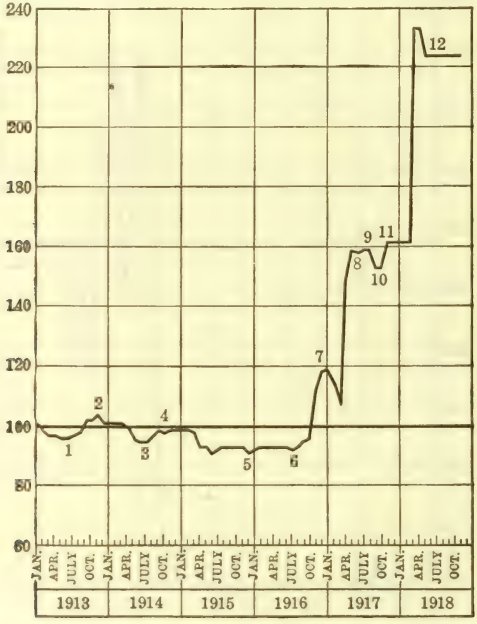

FIGURE 7.—Relative prices realized for bituminous coal produced in the Mount Olive district, Ill., by months, 1913–1918.

Production, 1917, 17,000,000 net tons. Average spot price, pre-war period, $1.24; average realized price $1.07.

1–6. The range of spot prices from summer to winter is, in normal times, marked in the Mount Olive district. In 1913 the lowest prices were in June, $1.03 (1), and the highest in November, $1.41 (2). In 1914 prices dropped to $1.05 in June (3), and rose to $1.26 in October and November (4). The lowest prices in 1915 were $1.04 in December (5) and the lowest in the summer of 1916, was $1.13 in July (6).

7. From September, 1916, to January, 1917, prices rose quickly, reaching a maximum for the six-year period of $3.25 in January, 1917 (7).

8. Prices prevailing in June, 1917, were quoted at $2.32 below the Peabody prices agreed upon as effective July 1 (8).

9. In July and August prices rose to $2.44 and $2.45, approaching the Peabody prices (9).

10. Prices fixed by the President toward the end of August are indicated at (10).

11. The advance of 45 cents authorized to cover the increase in wages of November, 1917, is shown at (11).

12. The general reduction of 10 cents a ton in the price of bituminous coal ordered by the Fuel Administrator, May 25, 1918, is indicated at (12).

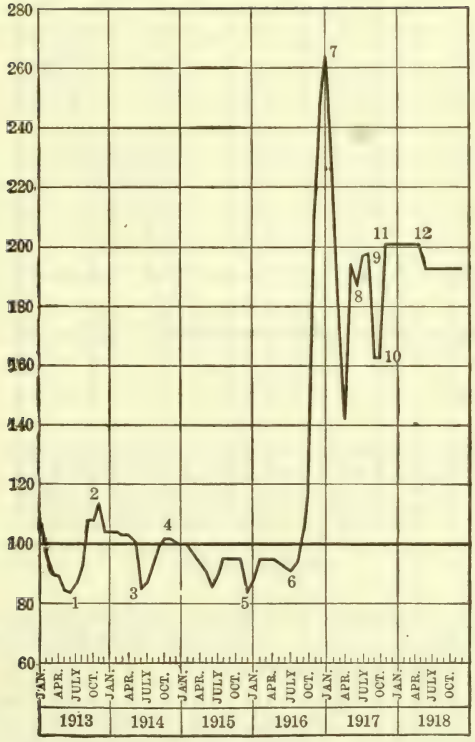

FIGURE 8.—Relative spot prices of bituminous coal produced in the Mount Olive district, Ill., by months, 1913–1918.

SPRINGFIELD DISTRICT, ILL.

Figure 10 shows the relative spot prices in this period compared with the average spot prices in the 12 months preceding the war, July, 1913, to June, 1914. Figure 9 shows the relative range in estimated average realization prices from all sales and includes both spot and contract transactions. The spot prices are taken from the Chicago market quotations of the Coal Age and the average realization prices from annual reports of operators compiled by the Geological Survey. Tables of actual prices and of the computed relative prices from which these diagrams were drawn are given on pages 64–66.

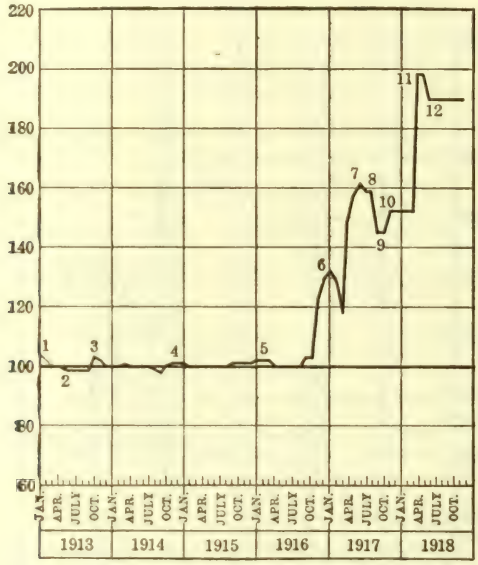

FIGURE 9.—Relative prices realized for bituminous coal produced in the Springfield district, Ill., by months, 1913–1918.

Production, 1917 (including Fulton, Peoria, and other northern districts), 27,000,000 net tons. Average spot price, pre-war period, $1.08; average realized price $1.26.

1–5. The spot prices for Springfield, Ill., coal in the period beginning with 1913 to the first half of 1916 ranged from $1.21 in January, 1913 (1), to $1.00 in May, 1913 (2), and $1.24 in February, 1916 (5), In October, 1913, the high point for the winter of 1913–14 was reached at $1.18 (3) and in the winter of 1914–15 the high quotation was reached in December, 1914, at $1.14 (4).

6. The price of Springfield coal began to rise in September, 1916, and reached a maximum of $3.52 in January, 1917 (6).

7. The spot prices for Springfield coal in June, 1917, averaged $3.05, slightly above the Peabody price fixed at the end of that month (7).

8. The prices in July and August under the Peabody agreement is shown at (8).

9. The reduction in price effected by the President's schedule is shown at (9).

10. The increase of 45 cents per ton allowed by the President to cover the advance in wages in November, 1917, is shown at (10).

11. The increase of 5 cents per ton in price of prepared sizes authorized on March 21, 1918, is shown at (11).

12. The general reduction of 10 cents per ton in the price of bituminous coal is shown at (12).

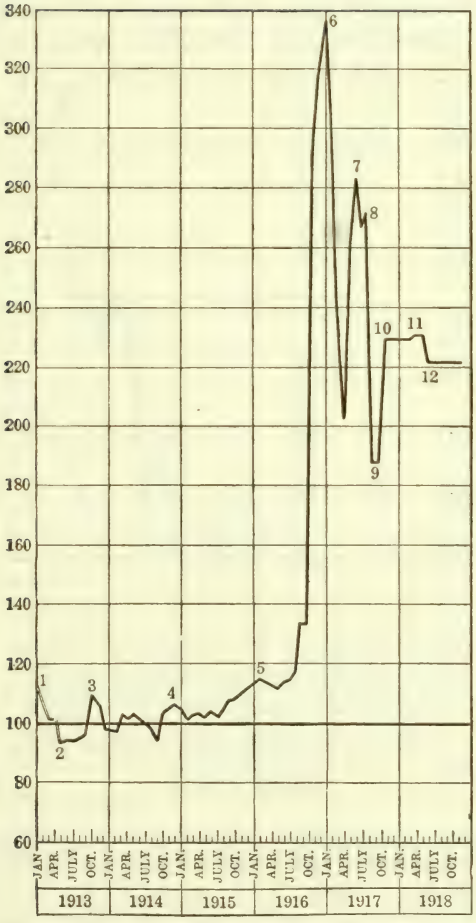

FIGURE 10.—Relative spot prices of bituminous coal produced in the Springfield district, Ill., by months, 1913–1918.

STANDARD DISTRICT, ILL.

Figure 12 shows the relative spot prices in this period compared with the average spot prices in the 12 months preceding the war, July, 1913, to June, 1914. Figure 11 shows the relative range in estimated average realization prices from all sales and includes both spot and contract transactions. The spot prices are taken from the St. Louis market quotations of the Coal Age and the average realization prices from annual reports of operators compiled by the Geological Survey. Tables of actual prices and of the computed relative prices from which these diagrams were drawn are given on pages 64–66.

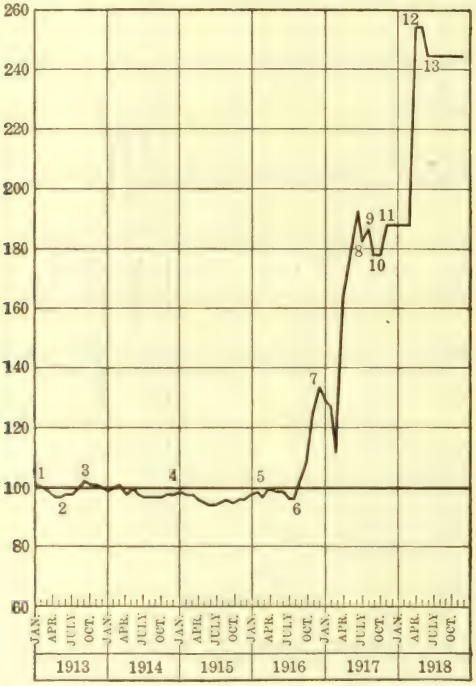

FIGURE 11.—Relative prices realized for bituminous coal produced in the Standard district, Ill., by months, 1913–1918.

Production, 1917, 13,000,000 net tons. Average spot price, pre-war period, 91 cents; average realized price, 98 cents.

1–6. From the beginning of 1913 to the middle of 1916, the prices of Standard district coal varied with the season of the year, the lower prices prevailing in the summer period and the higher prices in the winter period. The curve for this period resembles in many respects that for prepared sizes of anthracite. The price in January, 1913, was quoted at 98 cents (1), in June and July at 83 cents (2), and in September 97 cents (3), which represents the maximum for the winter of 1913–14. The maximum for the winter of 1914–15 was reached in January, 1915, at 93 cents (4). The maximum for the winter of 1915–16 was reached in February, 1916, at $1.02 (5). The low price for the summer of 1916, was 86 cents in May (6).

7. In September, 1916, the price in coal from the Standard district began to rise and a maximum was reached in December, 1916, at $2.87 (7).

8. The price declined in the early part of 1917 and in April reached a minimum for the year of $1.31; in June was $1.73 (8).

9. The quotations for July and August did not reach the maximum set by the Peabody agreement, the price in August averaging $2.43 (9).

10. The price fixed by the President on August 21, 1917, is shown at (10).
11. The advance of 45 cents authorized to cover the wage advance in November, 1917, is indicated at (11).

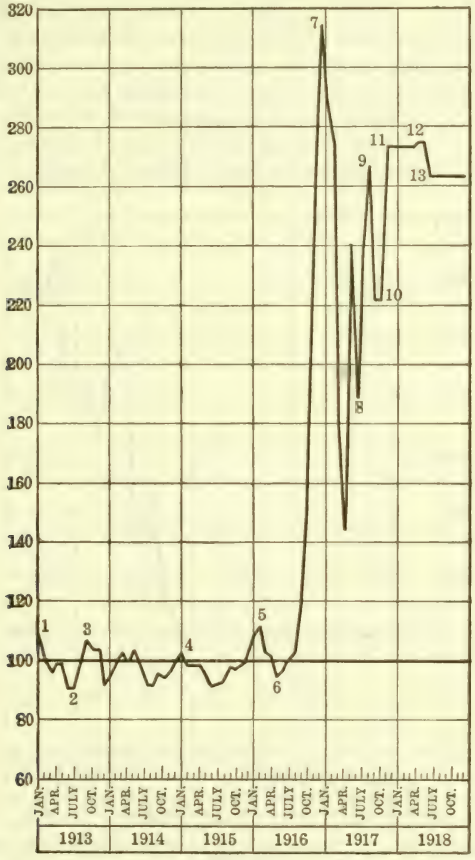

FIGURE 12.—Relative spot prices of bituminous coal produced in the Standard district, Ill., by months, 1913–1918.

12. An increase of 5 cents per ton on prepared sizes, authorized on March 21, 1918, is shown at (12).
13. The general reduction of 10 cents in the price of bituminous coal ordered on May 25, 1918, is shown at (13).

CLINTON DISTRICT, IND.

Figure 14 shows the relative spot prices in the period compared with the average spot prices in the 12 months preceding the war, July, 1913, to June, 1914. Figure 13 shows the relative range in estimated average realization prices from all sales and includes both spot and contract transactions. The spot prices are taken from the Chicago market quotations of the Coal Age and the average realization prices from annual reports of operators compiled by the Geological Survey. Tables of actual prices and of the computed relative prices from which these diagrams were drawn are given on pages 64–66.

FIGURE 13.—Relative prices realized for bituminous coal produced in the Clinton district, Ind., by months, 1913–1918.

Production of State of Indiana, 1917, 26,500,000 net tons. Average spot price, pre-war period, $1.13; average realized price, $1.10.

1, 2, and 3. The price of Clinton coal ranged from $1.25 in April, 1913 (1), to $1.03 in July and August, 1915 (2), and $1.23 in February, 1916 (3), in the period before the general rise in the prices of bituminous coal that took place in the latter part of 1916.

4. The rise in price of Clinton coal that began in August and September, 1916, reached a maximum in January, 1917, of the average spot price in that month of $3.57 (4).

5. In May and June, 1917, spot prices for Clinton coal were around $3.12 (5).

6. The Peabody prices (6) were slightly lower than the maximum quotations in May and June.

7. The prices fixed by the President are indicated at (7).

8. The increase of 45 cents per ton allowed operators to cover the advance in wages in November is shown at (8).

9. An advance of 5 cents per ton on prepared sizes, authorized by the Fuel Administrator on May 1, 1918, is indicated at (9).

10. The general reduction of 10 cents per ton in the price of bituminous coal ordered by the Fuel Administrator on May 25, 1918, is shown at (10).

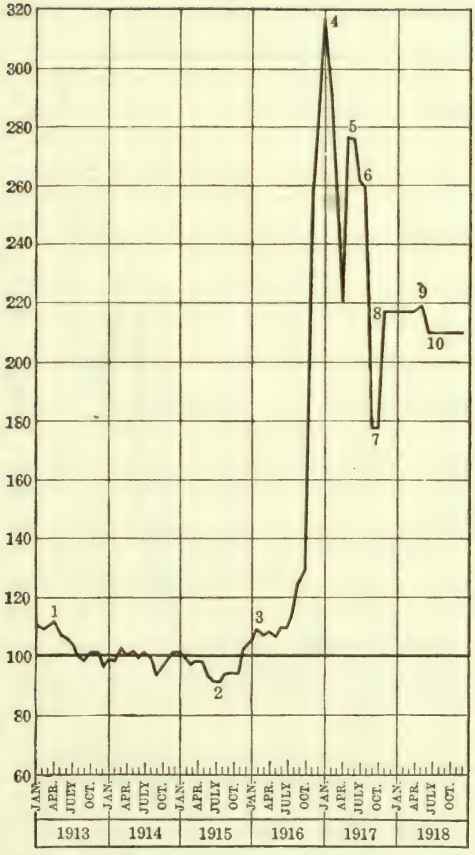

FIGURE 14.—Relative spot prices of bituminous coal produced in the Clinton district, Ind., by months 1913–1918.

EASTERN KENTUCKY.

Figure 16 shows the relative spot prices in this period compared with the average spot prices in the 12 months preceding the war, July 1913, to June, 1914. Figure 15 shows the relative range in estimated average realization prices from all sales and includes both spot and contract transactions. The spot prices are taken from the Louisville market quotations of the Coal Age and the average realization prices from annual reports of operators compiled by the Geological Survey. Tables of actual prices and of the computed relative prices from which these diagrams were drawn are given on pages 64–66.

FIGURE 15.—Relative prices realized for bituminous coal produced in the eastern Kentucky district, by months, 1913–1918.

Production, 1917, 17,000,000 net tons. Average spot price, prewar period, $1.52; average realized price, $1.11.

1–7. The seasonal character of the market for eastern Kentucky coal is well shown by the diagram for the period 1913 to the middle of 1916. The low points (1, 3, 5, and 7) occurred in the summer time and the high points (2, 4, and 6) in the fall and winter time. The highest spot price reached in the years 1913–1915 was in November, 1913, $1.89. The maximum in the winter of 1914–15 was in October, 1914, $1.58 (4). The maximum reached in 1915 was $1.71 in December (6). The lowest price in 1913 was $1.29 in May (1); the lowest price in 1914 was $1.23 in April (3), and the lowest price in 1915 and in the six-year period covered in this report was $1.16 in March, 1915 (5). From the high level of December, 1915, the spot prices of eastern Kentucky coal declined to $1.33 in May and June, 1916 (7).

8. The spot price for eastern Kentucky coal began to rise in September, 1916, and in December reached a maximum for that year of $4.17. The following June the price reached $4.72, the highest average monthly quotation recorded in the six-year period (8).

9. The Peabody price was quoted in July and August (9).

10. The prices fixed by the President on August 21, 1917, are shown at (10).

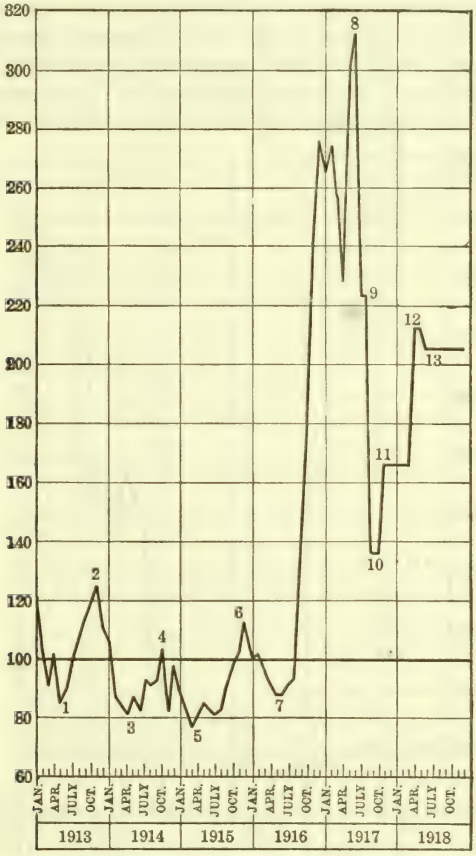

FIGURE 16.—Relative spot prices of bituminous coal produced in the eastern Kentucky district, by months, 1913–1918.

11. The wage increase of November, 1917, for which the operators were permitted to add 45 cents per ton to the price of coal at the mine is indicated at (11).

12. An increase of 70 cents per ton on all sizes was authorized by the Fuel Administrator on April 4, 1918 (12).

13. The general reduction of 10 cents per ton in the average price of bituminous coal is shown at (13).

WESTERN KENTUCKY.

Figure 18 shows the relative spot prices in this period compared with the average spot prices in the 12 months preceding the war, July, 1913, to June, 1914. Figure 17 shows the relative range in estimated average realization prices from all sales and includes both spot and contract transactions. The spot prices are taken from the Louisville market quotations of the Coal Age and the average realization prices from annual reports of operators compiled by the Geological Survey. Tables of actual prices and of the computed relative prices from which these diagrams were drawn are given on pages 64–66.

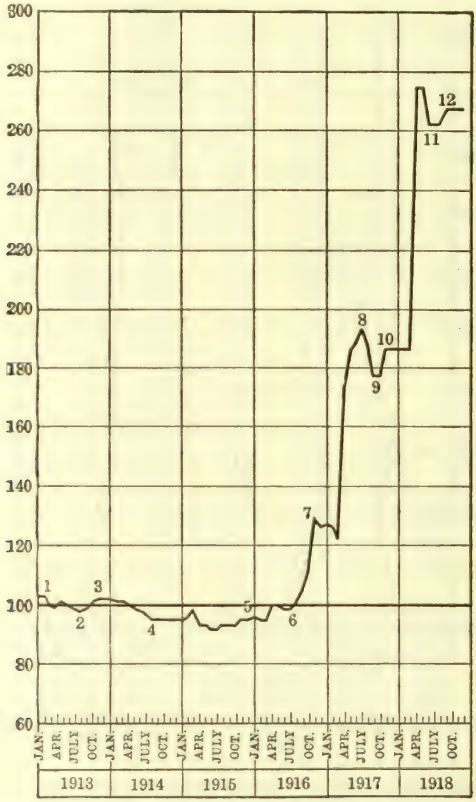

FIGURE 17.—Relative prices realized for bituminous coal produced in the western Kentucky district, by months, 1913–1918.

Production, 1917, 10,000,000 net tons. Average spot price, prewar period, 98 cents; average realized price, 89 cents.

1–6. From the beginning of 1913 to the middle of 1916, when the general rise in the prices of bituminous coal began, the highest price of free coal quoted for western Kentucky was in January, 1913, $1.12 (1). In the summer of 1913 the spot price of western Kentucky coal declined to 88 cents in August (2) and rose again to $1.07 in November and December (3). From this point the price declined steadily to a low point for the period under discussion of 81 cents in October, 1914 (4). In the spring of 1915 the price rose, and after a small recession during the summer of 1915, increased to a maximum of $1.06 in January, 1916 (5). The price again declined to a minimum in 1916 of 86 cents a ton in July (6).

7. From August to November, 1916, the price rose to a maximum of $2.70 (7). The spot price, however, declined to $1.72 in April, 1917, and had risen to but $2.62 in June, when the Peabody price was fixed at $3 for western Kentucky coal.

8. The western Kentucky coal was not quoted in July at the maximum established by the Peabody agreement, but rose only to $2.81 (8).

9. The price fixed by the President is indicated at (9).

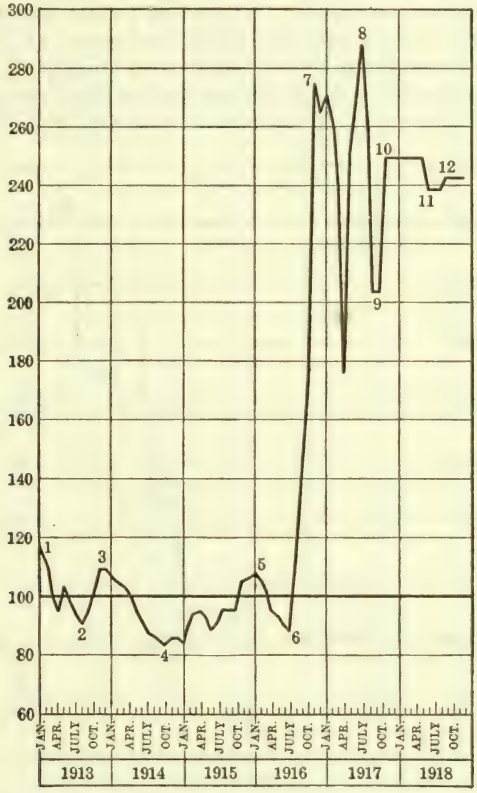

FIGURE 18.—Relative spot prices of bituminous coal produced in the western Kentucky district, by months, 1913-1918.

10. The wage advance in November, to cover which the operators were permitted to add 45 cents a ton at the mine, is shown at (10).

11. The general reduction of 10 cents per ton in the price of bituminous coal on May 25, 1918, is indicated at (11).

12. On August 23, 1918, the Fuel Administrator authorized an advance of 5 cents per ton on run-of-mine and prepared sizes indicated at (12).

GEORGES CREEK DISTRICT, MD.

Figure 20 shows the relative spot prices in this period compared with the average spot prices in the 12 months preceding the war, July, 1913, to June, 1914. Figure 19 shows the relative range in estimated average realization prices from all sales and includes both spot and contract transactions. The spot prices are taken from the Boston market quotations of the Coal Age and the average realization prices from annual reports of operators compiled by the Geological Survey. Tables of actual prices and of the computed relative prices from which these diagrams were drawn are given on pages 64–66.

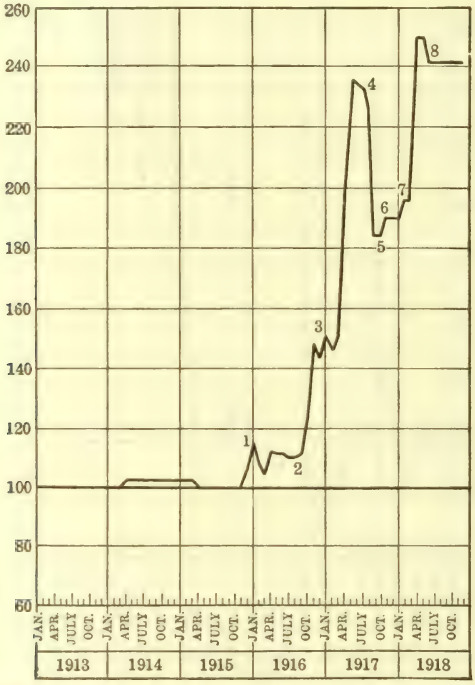

FIGURE 19.—Relative prices realized for bituminous coal produced in the Georges Creek district, Md., by months, 1913–1918.

Production, 1917, 4,000,000 net tons. Average spot price, pre-war period, $1.54; average realized price, $1.14.

1, 2. The quotations carried on the Boston market for Georges Creek coal were uniformly $1.54 through 1913, 1914, and until the end of 1915. In January, 1916, the price rose to $2.50 (1), but declined from the first part of 1916 to $1.47 in August (2).

3, 4. Beginning with September, 1916, the price rose rapidly and reached a maximum of $5.72 in January, 1917, around which the price fluctuated until in June, at the time the Peabody prices were fixed, Georges Creek was quoted in Boston at $5.55. The prices in July and August were $5.46 and $5, indicated at (4).

5. The prices fixed by the President on August 21, 1917, represent a considerable drop below the prevailing quotations (5).

6. The advance of 45 cents per ton authorized to cover the increase in wages in November, 1917, are indicated at (6).

7. On January 31, 1918, an advance of 40 cents per ton on all sizes was authorized by the Fuel Administrator (7).

8. The general reduction of 10 cents per ton ordered by the Fuel Administrator on May 25, 1918, is indicated at (8).

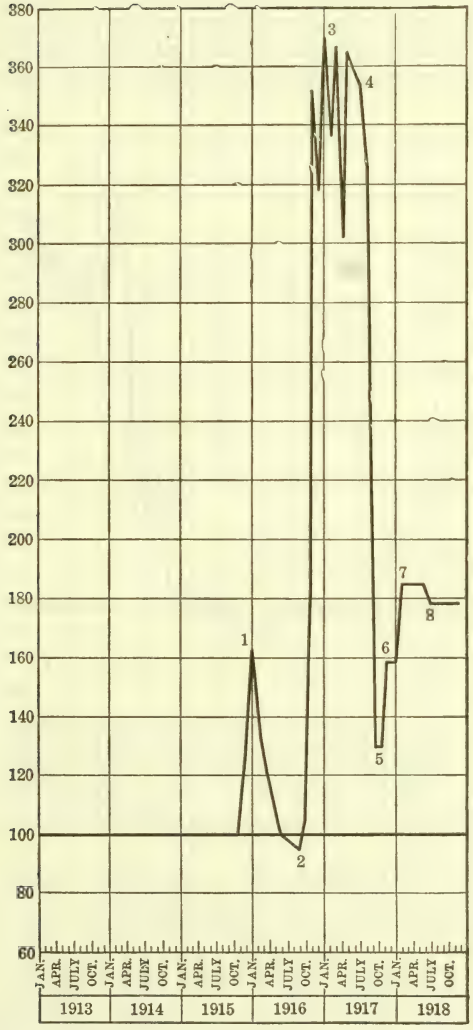

FIGURE 20.—Relative spot prices of bituminous coal produced in the Georges Creek district, Md., by months, 1913-1918.

HOCKING DISTRICT, OHIO.

Figure 22 shows the relative spot prices in this period compared with the average spot prices in the 12 months preceding the war, July, 1913, to June, 1914. Figure 21 shows the relative range in estimated average realization prices from all sales and includes both spot and contract transactions. The spot prices are taken from the Columbus and Detroit market quotations of the Coal Age and the average realization prices from annual reports of operators compiled by the Geological Survey. Tables of actual prices and of the computed relative prices from which these diagrams were drawn are given on pages 64–66.

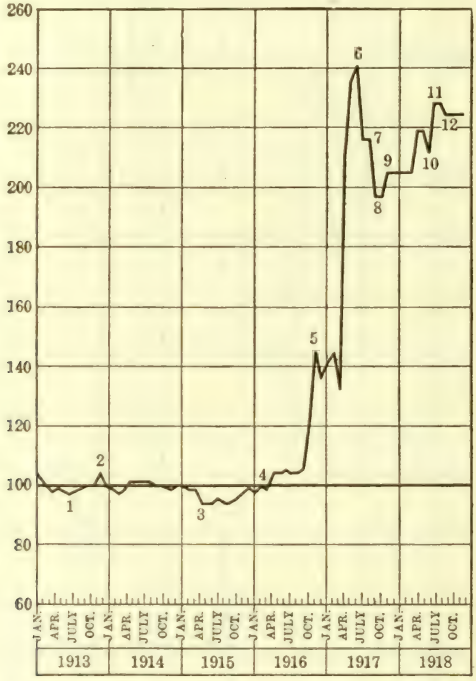

FIGURE 21.—Relative prices realized for bituminous coal produced in the Hocking district, Ohio, by months, 1913–1918.

Production, 1917 (including all of southern Ohio), 14,000,000 net tons. Average spot price, pre-war period, $1.19; average realized price, $1.16.

1–4. Spot prices for southern Ohio coal were generally higher than in the No. 8 district in 1913–1915, the highest, $1.41, in November, 1913 (2), following the low price of $1.10 in June (1), and succeeded by the lowest in the three years of $1.06 in March, 1915 (3). A slow but steady increase in prices is noted through the last three-quarters of 1915 that reached $1.25 in February, 1916 (4).

5, 6. A dull market in the early part of the summer of 1916 was enlivened when early in August a flood on Cabin Creek, W. Va., disabled a considerable portion of the Kanawha field. Consumers in Ohio with contracts in this field began bidding for coal on the Columbus market and prices of Hocking coal began to rise, under the stimulation of this movement, in September. The highest spot price was recorded in November, $4.74 (5). The spot price fluctuated greatly during the winter and spring of 1917 and was at $4.32 (6) in June when the Peabody price was fixed.

7. The drop from the June price to the Peabody price is shown at (7).
8. The President's price (8) was considerably below the Peabody agreement.
9. The wage advance in November, for which the operators were allowed to add 45 cents a ton to the mine price, is shown at (9).

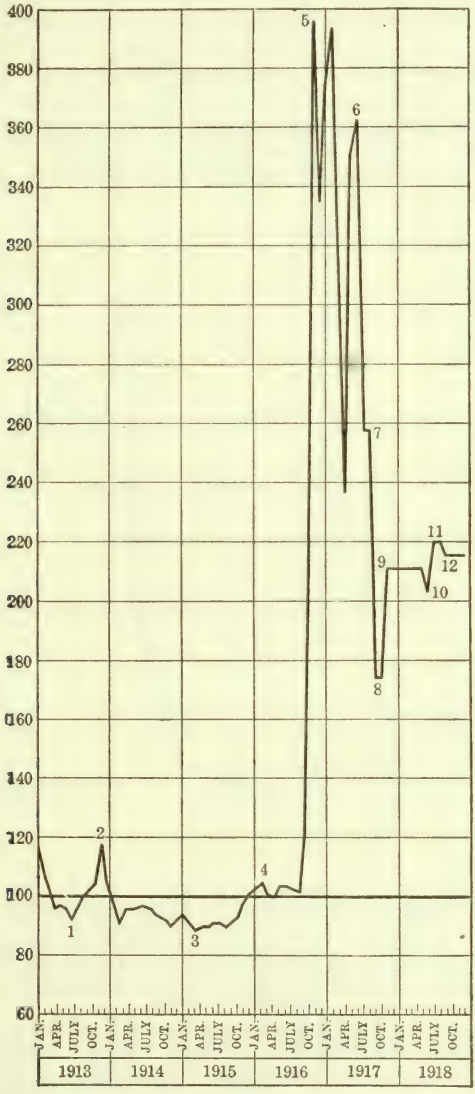

FIGURE 22.—Relative spot prices of bituminous coal produced in the Hocking district, Ohio, by months, 1913–1918.

10. The general reduction of 10 cents per ton, May 25, 1918, is shown at (10).
11. The order of June 29, 1918, permitted an increase of 20 cents a ton on all sizes of Hocking coal (11).
12. These prices were reduced 5 cents a ton by the order of August 23, 1918 (12).

PITTSBURGH NO. 8 DISTRICT, OHIO.

Figure 24 shows the relative spot prices in this period compared with the average spot prices in the 12 months preceding the war, July, 1913, to June, 1914. Figure 23 shows the relative range in estimated average realization prices from all sales and includes both spot and contract transactions. The spot prices are taken from the Columbus and Detroit market quotations of the Coal Age and the average realization prices from annual reports of operators compiled by the Geological Survey. Tables of actual prices and of the computed relative prices from which these diagrams were drawn are given on pages 64–66.

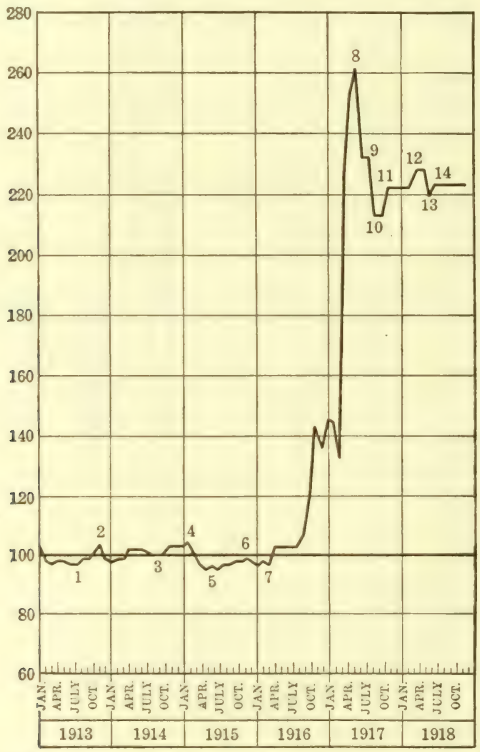

FIGURE 23.—Relative prices realized for bituminous coal produced in the Pittsburgh No. 8 district, Ohio, by months, 1913–1918.

Production, 1917 (including northern Ohio), 25,000,000 net tons. Average spot price, pre-war period, $1.12; average realized price, $1.09.

1–7. The spot price of Ohio No. 8 coal in the years 1913–1915 ranged from 98 cents to $1.28 a ton. In 1913 the low point was in July (1) at $1.03 a ton and the high point at $1.28 in November (2). From this figure in November, 1913, the price declined to $1.02 in August and September, 1914 (3), and during the winter advanced to $1.17 in February, 1915 (4), the highest point during that year. The lowest price recorded in the six-year period 1913–1918 was in May, 1915, 98 cents (5). Prices rose slowly during the summer and fall of 1915 to $1.12 in December (6) but receded to $1.06 in March, 1916.

8 and 9. With the beginning of the coal year, 1916–1917, prices of coal in this district rose slightly, but the spectacular rise did not begin until September. By November the prices had risen to $4.74, and in January, 1917, the maximum of $4.93 was reached (8). A drop in April to $2.76 was followed by a new rise to $4.37 in June (9).

10. The Peabody price of $3 was agreed upon, effective July 1, 1917 (10), and this price was quoted during July and in August until the President fixed prices.

11. The price fixed by the President, August 21, was at a $2 base for mine-run coal (11).

12. The wage advance, for which 45 cents a ton was allowed the operator, is shown at (12).

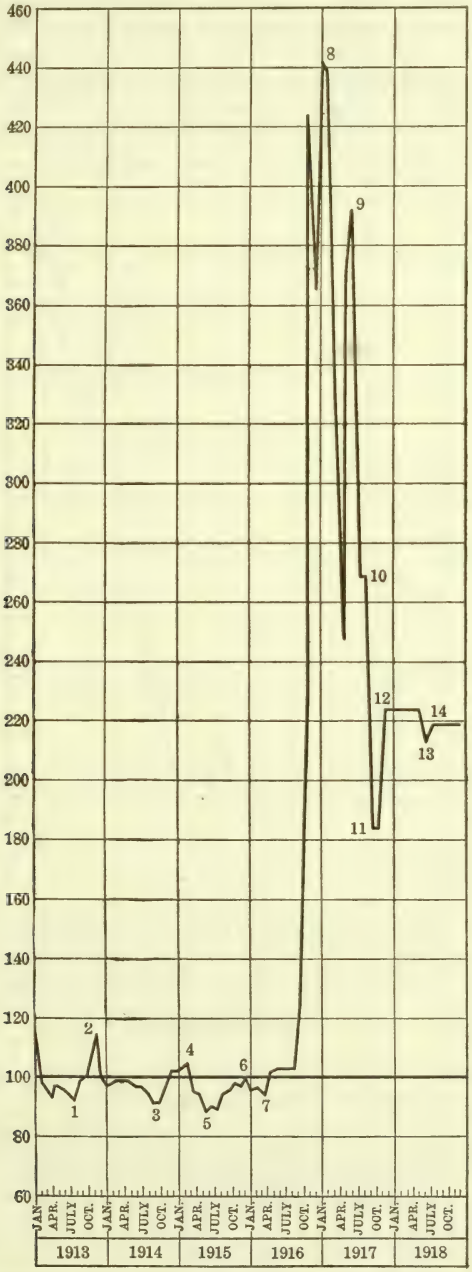

FIGURE 24.—Relative spot prices of bituminous coal produced in the Pittsburgh No. 8 district, Ohio, by months, 1913–1918.

13. The general reduction of 10 cents in the price of all bituminous coal on May 25 is shown at (13).

14. An increase of 25 cents a ton on slack coal on June 29, 1918 is recorded at (14).

CLEARFIELD DISTRICT, PA.

Figure 26 shows the relative spot prices in this period compared with the average spot prices in the 12 months preceding the war, July, 1913, to June, 1914. Figure 25 shows the relative range in estimated average realization prices from all sales and includes both spot and contract transactions. The spot prices are taken from the Boston market quotations of the Coal Age and the average realization prices from annual reports of operators compiled by the Geological Survey. Tables of actual prices and of the computed relative prices from which these diagrams were drawn are given on pages 67-69.

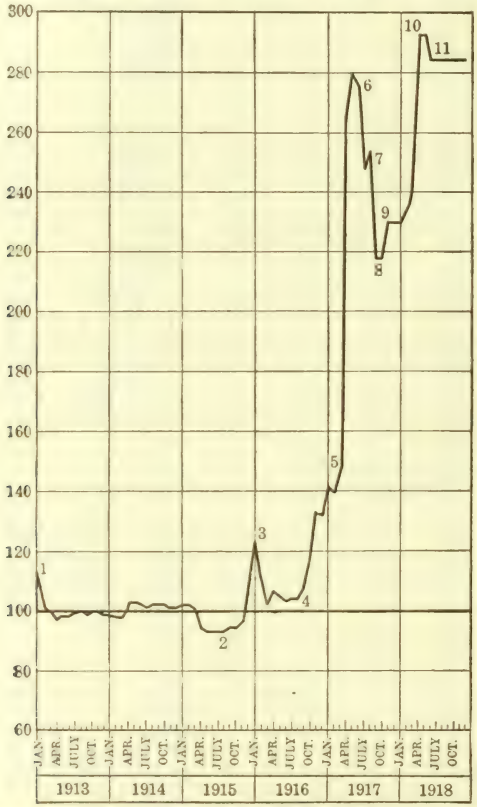

FIGURE 25.—Relative prices realized for bituminous coal produced in the Clearfield district, Pa., by months, 1913-1918.

Production, 1917, 30,000,000 net tons. Average spot price, pre-war period, $1.12; average realized price, $1.04.

1–4. From $1.71 in January, 1913 (1), current quotations on Clearfield coal dropped to an average in the remainder of 1913, through 1914, and until November, 1915, of around $1.05 and $1.15. The lowest point reached was in the period from May to August, 1915, $1 (2). In January, 1916, the price rose to $2.59 (3), but declined again to $1.16 in June (4).

5. Prices began to rise rapidly in August, 1916, and reached a maximum of $5.16 in March, 1917 (5).

6. The price in June, when the Peabody prices were agreed upon, was quoted at $4.89 (6).

7. The prices in July and August, 1917, during the period in which the Peabody agreement was in effect, are indicated at (7).

8. Prices fixed by the President in August are shown at (8).

9. The increase of 45 cents a ton allowed to cover the wage advance of November, 1917, is indicated at (9).

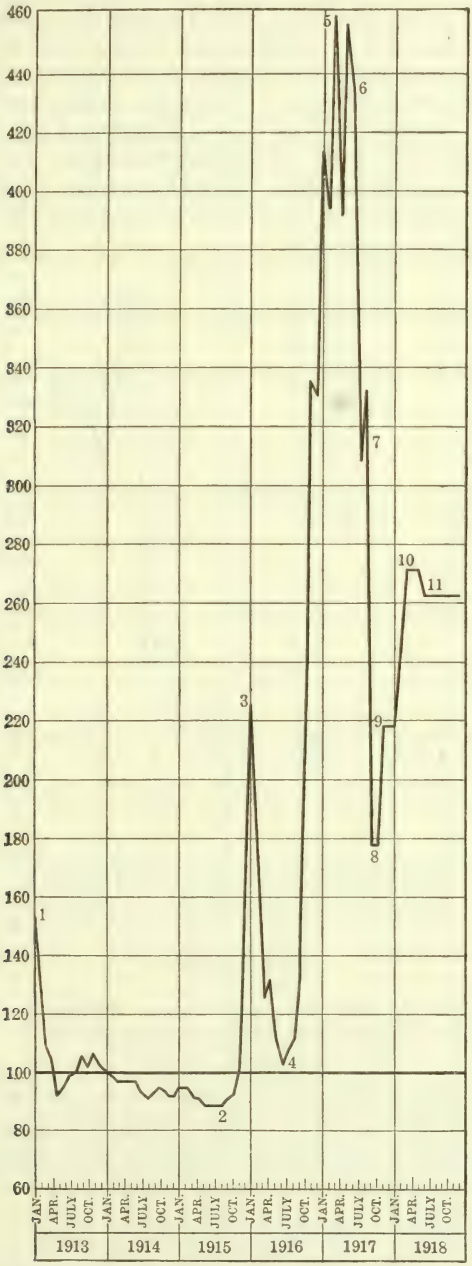

FIGURE 26.—Relative spot prices of bituminous coal produced in the Clearfield district, Pa., by months, 1913–1918.

10. The increase allowed central Pennsylvania by the Fuel Administrator February 16, 1918, raised the price 60 cents a ton (10).

11. The general reduction of 10 cents a ton in the price of bituminous coal by the Fuel Administrator May 25, 1918, is shown at (11).

PITTSBURGH DISTRICT, PA.

Figure 28 shows the relative spot prices in this period compared with the average spot prices in the 12 months preceding the war, July, 1913, to June, 1914. Figure 27 shows the relative range in estimated average realization prices from all sales and includes both spot and contract transactions. The spot prices are taken from the Pittsburgh market quotations of the Coal Age and the average realization prices from annual reports of operators compiled by the Geological Survey. Tables of actual prices and of the computed relative prices from which these diagrams were drawn are given on pages 67-69.

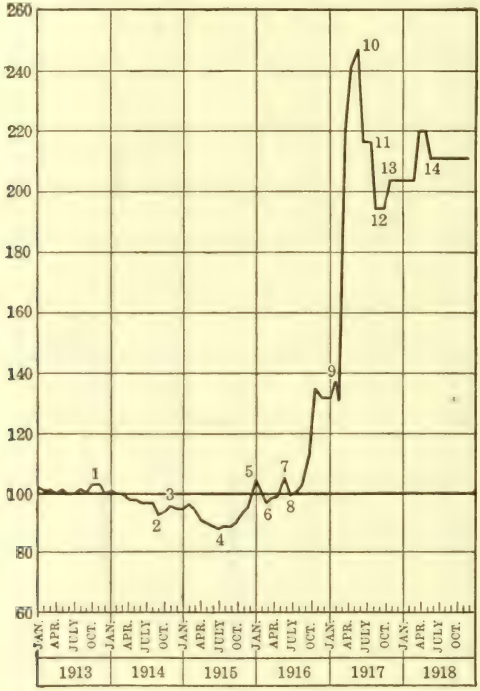

FIGURE 27.—Relative prices realized for bituminous coal produced in the Pittsburgh district, Pa., by months, 1913–1918.

Production, 1917, 51,000,000 net tons. Average spot price, prewar period, $1.26; average realized price, $1.12.

1–4. The spot price of Pittsburgh coal declined from $1.36 in October and November, 1913 (1), to 93 cents in July, 1915 (4), with a temporary rise in the winter of 1914–15 from $1 in September (2) to $1.14 in November, 1914 (3).

5–8. In the winter of 1915–16 and again in the summer of 1916 there were temporary rises in price. Quotations in Januray, 1916, were $1.58 (5), followed by $1.23 in April (6) and a high mark for the summer period of $1.72 in June (7). Prices declined again to $1.34 in July (8).

9. By October, 1916, prices were again well on the upward trend and in February, 1917, reached the maximum for the six-year period of $5.21 (9).

10. In June, when the Peabody prices were agreed upon, quotations averaged $4.97 (10).

11. The Peabody prices are indicated at (11).

12. The prices fixed by the President are shown at (12).

13. The increase of 45 cents per ton allowed to cover the advance in wages is shown at (13).

14. The general reduction of 10 cents a ton on all bituminous coal ordered May 25, 1918, is indicated at 14).

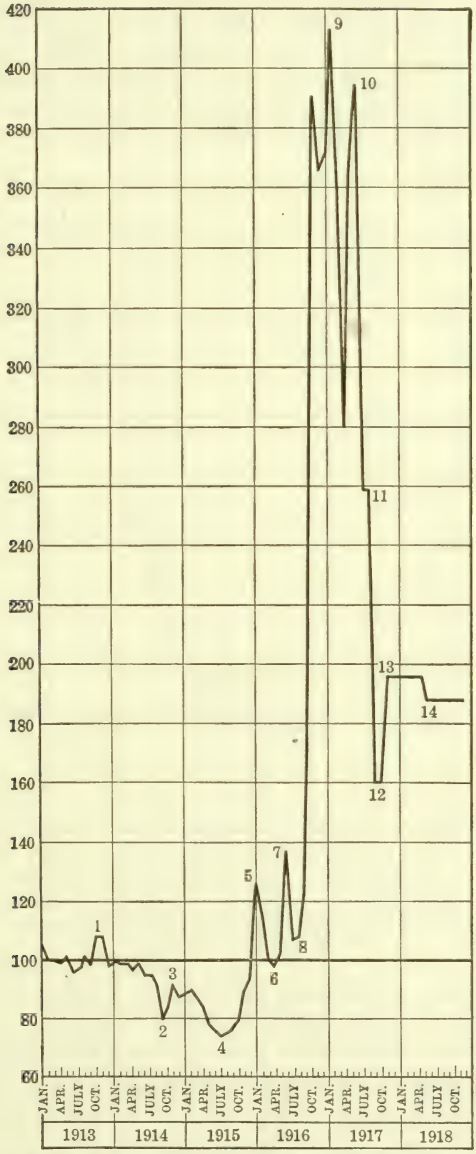

FIGURE 28.—Relative spot prices of bituminous coal produced in the Pittsburgh district, Pa., by months, 1913–1918.

SOMERSET AND CAMBRIA COUNTIES, PA.

Figure 30 shows the relative spot prices in this period compared with the average spot prices in the 12 months preceding the war, July, 1913, to June, 1914. Figure 29 shows the relative range in estimated average realization prices from all sales and includes both spot and contract transactions. The spot prices are taken from the Boston market quotations of the Coal Age and the average realization prices from annual reports of operators compiled by the Geological Survey. Tables of actual prices and of the computed relative prices from which these diagrams were drawn are given on pages 67-69.

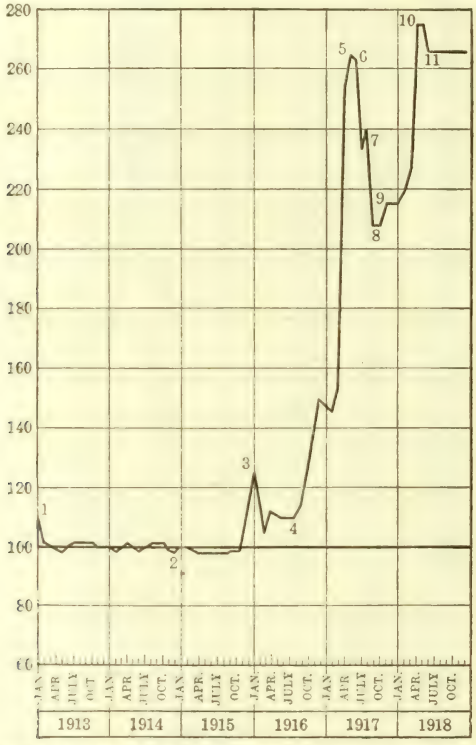

FIGURE 29.—Relative prices realized for bituminous coal produced in Somerset and Cambria counties, Pa., by months, 1913-1918.

Production, 1917, 29,000,000 net tons. Average spot price, pre-war period, $1.30; average realized price, $1.11.

1-4. From $1.88 in January, 1913 (1), current quotations on Somerset and Cambria coal dropped to an average in the remainder of 1913, through 1914, and until November, 1915, of around $1.25. The lowest point reached was in December, 1914, $1.18 (2). In January, 1916, the price rose to $2.79 (3), but declined again to $1.38 in June and July (4).

5. Prices began to rise rapidly in August, 1916, and reached a maximum of $5.48 in March, 1917 (5).

6. The price in June, 1917, when the Peabody prices were agreed upon, was quoted at $5.11 (6).

7. The prices in July and August, 1917, during the period in which the Peabody agreement was in effect, are indicated at (7).

8. Prices fixed by the President in August are shown at (8).
9. The increase of 45 cents a ton allowed to cover the wage advance of November, 1917, is indicated at (9).

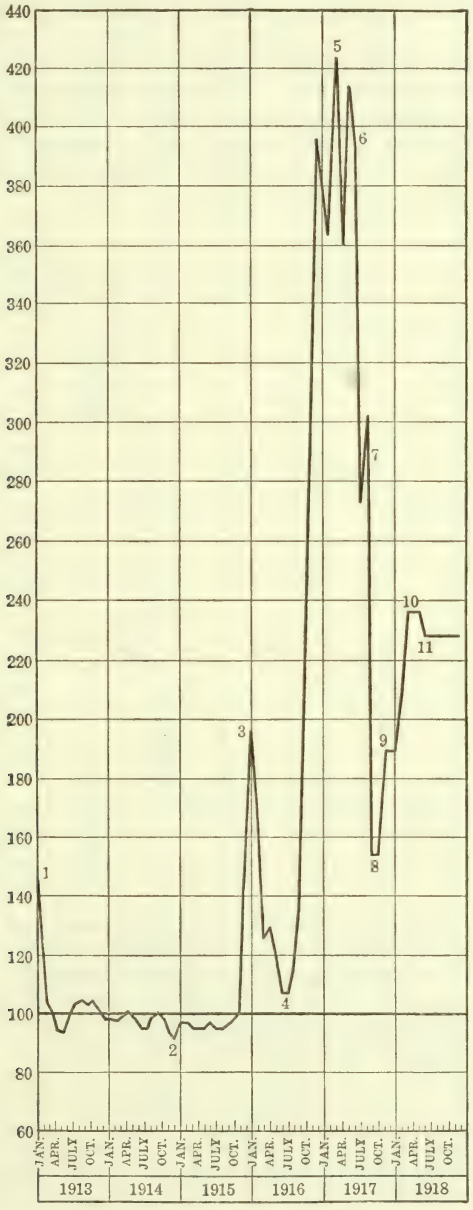

FIGURE 30.—Relative spot prices of bituminous coal produced in Somerset and Cambria counties, Pa., by months, 1913-1918.

10. The increase allowed central Pennsylvania by the Fuel Administrator February 16, 1918, raised the price 60 cents a ton (10).
11. The general reduction of 10 cents a ton in the price of bituminous coal by the Fuel Administrator May 25, 1918, is shown at (11).

KANAWHA DISTRICT, W. VA.

Figure 32 shows the relative spot prices in this period compared with the average spot prices in the 12 months preceding the war, July, 1913, to June, 1914. Figure 31 shows the relative range in estimated average realization prices from all sizes and includes both spot and contract transactions. The spot prices are taken from the Columbus, Ohio, market quotations of the Coal Age and the average realization prices from annual reports of operators compiled by the Geological Survey. Tables of actual prices and of the computed

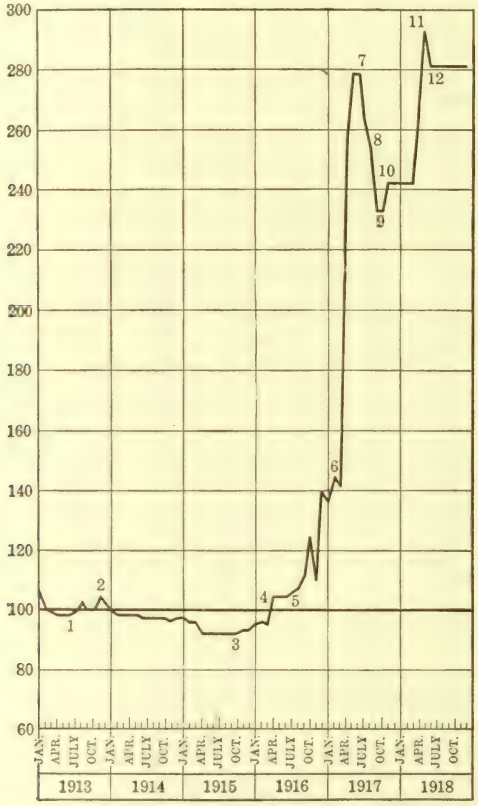

FIGURE 31.—Relative prices realized for bituminous coal produced in the Kanawha district, W. Va., by months, 1913–1918.

relative prices from which these diagrams were drawn are given on pages 67-69.

Production, 1917 (including Logan and Kenova-Thacker), 28,000,000 net tons. Average spot price, pre-war period, $1.16; average realized price 94 cents.

1–5. From a spot price of $1.39 in January, 1913, the price of Kanawha coal dropped to $1.06 in June (1) and rose to $1.37 in November (2). From this peak the price declined in 1914, reaching a minimum of $1.02 in the summer of 1915 (3). In the winter of 1915–16 the price rose to $1.20 in February (4). From April to August the price ranged from 96 cents to $1.21. There was a sudden upward rise of prices in the Kanawha district again in September, in which the average spot price was $1.59.

6, 7. The maximum in the period of high prices was reached in February, 1917, in which month the average spot price was $4.15. The price dropped off in March and April but in May again reached $4.15 and in June was $4.11 (7).

8. The Peabody agreement brought the price for free coal in the Kanawha district to around $3.00 (8).

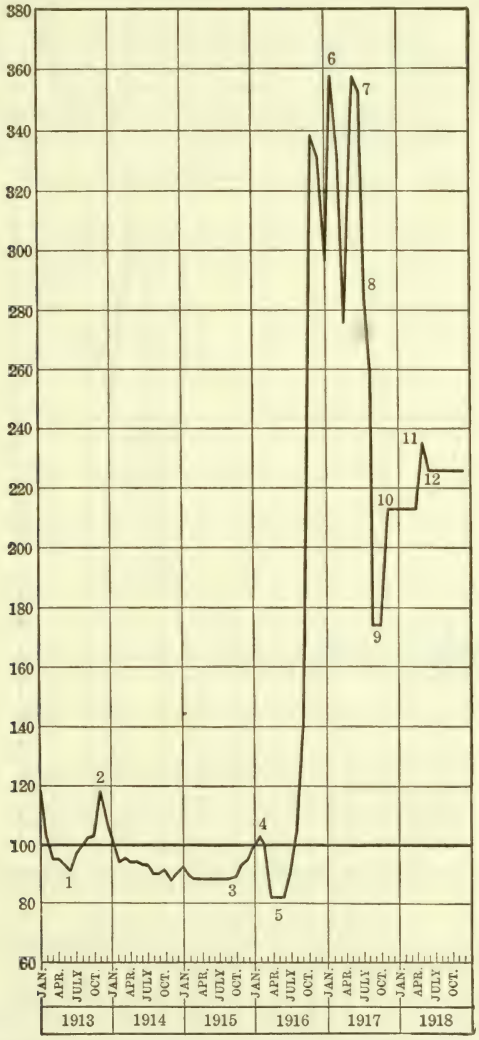

FIGURE 32.—Relative spot prices of bituminous coal produced in the Kanawha district, W. Va., by months, 1913–1918.

9. The prices fixed by the President on August 21, 1917, were considerably below those agreed upon in June by the Lane-Peabody committee (9).

10. The increase in wages authorized in November, to cover which the operators were permitted to add 45 cents a ton, is shown at (10).

11. On April 20, 1918, the Fuel Administrator authorized an increase in price of Kanawha coal of 25 cents a ton on all sizes (11).

12. The general reduction in all mine prices for bituminous coal of 10 cents a ton, ordered on May 25, 1918, is shown at (12).

POCAHONTAS AND NEW RIVER FIELDS, W. VA.

Figure 34 shows the relative spot prices in this period compared with the average spot prices in the 12 months preceding the war, July, 1913, to June, 1914. Figure 33 shows the relative range in estimated average realization prices from all sales and includes both spot and contract transactions. The spot prices are taken from the Boston market quotations of the Coal Age and the average realization prices from annual reports of operators compiled by the Geological Survey. Tables of actual prices and of the computed relative prices from which these diagrams were drawn are given on pages 67–69.

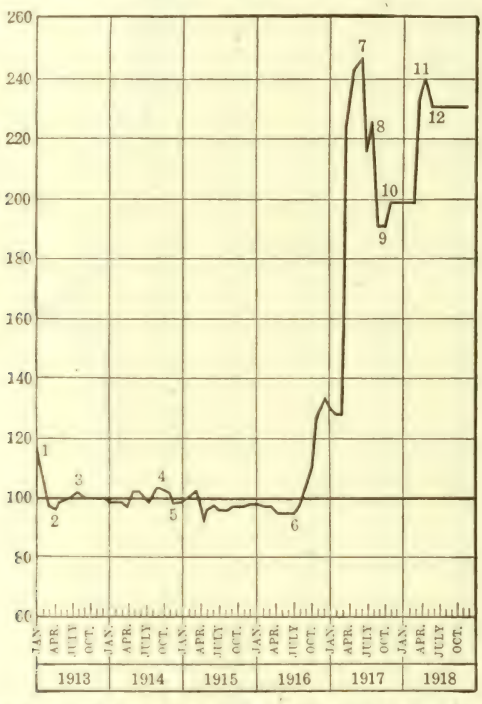

FIGURE 33.—Relative prices realized for bituminous coal produced in the Pocahontas and New River fields, W. Va., by months, 1913–1918.

Production, 1917, 40,000,000 net tons. Average spot price, pre-war period, $1.30; average realized price, $1.08.

1–6. The highest spot price for Pocahontas and New River coal in the years 1913–1915 was $1.85 in January, 1913 (1). The price rapidly dropped, however, to $1.16 in March (2), but recovered to the maximum for the remaining portion of the three years of $1.39 in July, 1913 (3). From this point the price suddenly declined until $1.12 was reached in July, 1914. The price rose to $1.33 in September, 1914 (4), but declined to $1.09 and $1.10 in November and December (5). With some fluctuations the price rose to $1.30 in January, 1916. The price declined from January, 1916, to June, the average price in June being $1.24 (6).

7. The prices of smokeless coal began to advance in July, 1916, and in August reached $1.54 and by December was quoted at $5.30. The maximum was reached in June, 1917, at $5.34 (7).

8. The Peabody prices were quoted in July, but under the pressure of buyers the quotations in August, 1917, were above the Peabody agreement (8).

9. The prices fixed by the President on August 21, 1917, was considerably below the Peabody price (9).

10. The advance in wages authorized in November, to cover which the operators were permitted to add 45 cents a ton, is shown at (10).

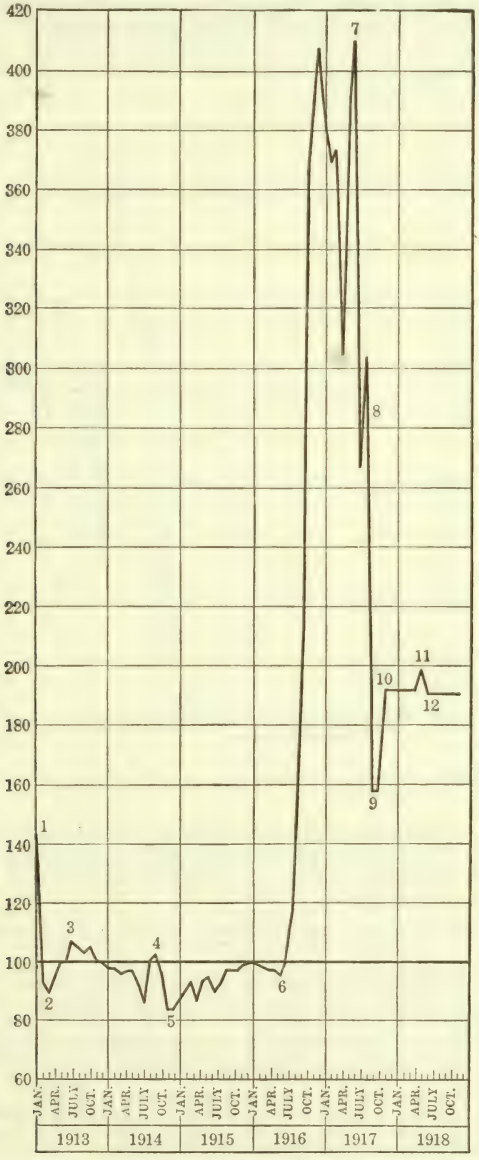

FIGURE 34.—Relative spot prices of bituminous coal produced in the Pocahontas and New River fields, W. Va., by months 1913–1918.

11. An increase of 20 cents a ton authorized for the New River district but not for the Pocahontas district, effective April 19, 1918, is shown at (11).

12. The general reduction of 10 cents a ton at the mine in all prices of bituminous coal, ordered by the Fuel Administrator on May 25, is shown at (12).

ALABAMA.

Figure 35 shows the relative spot prices in this period, compared with the average spot prices in the 12 months preceding the war, July, 1913, to June, 1914. The spot prices from January, 1913, to June, 1917, represent a weighted average of a series of quotations for high and low grade steam coal obtained through the courtesy of S. L. Yerkes, of Birmingham, Ala.

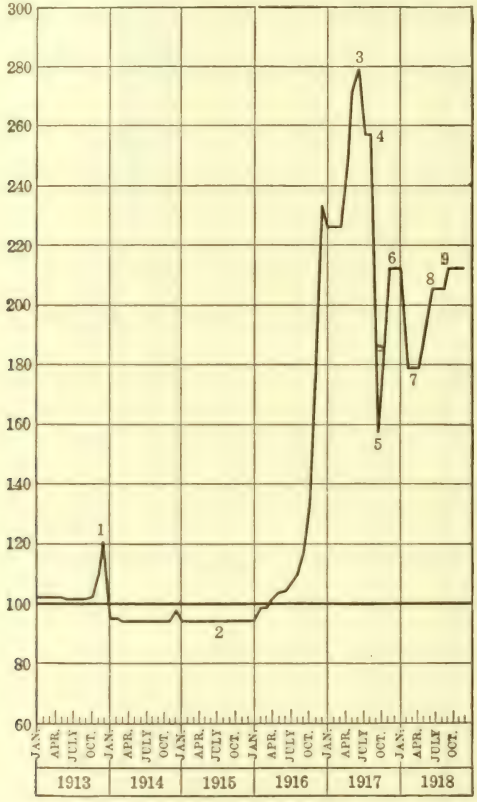

FIGURE 35.—Relative spot prices of Alabama steam coal, by months, 1913–1918.

Production of coal in Alabama in 1917, 20,000,000 net tons. Average spot price of steam coal, pre-war period, $1.33.

1, 2. A maximum average price of $1.61 (1) was quoted in December, 1913, for the three years, 1913, 1914, and 1915. Through 1915 the price did not vary from an average of $1.25 (2).

3. Beginning early in 1916, the price of steam coal in Alabama steadily rose, reaching a maximum in December of $3.11. After a temporary decline, the price rose to $3.71 (3) in June, 1917, the maximum in the six-year period.

4. The Peabody prices were established in July and are shown at (4).

5. The drop to the level set by the President's prices of August 21, 1917, is shown at (5).

6. On October 1, 1917 an increase in mine prices of Alabama coal was authorized by the Fuel Administrator and on October 29 (6) an increase of 45 cents a ton was allowed to cover the advance in wages allowed November 1.

7. On February 6 the 45 cent increase was taken off and the average price was decreased to (7).

8. Effective May 15, 1918, producers in Alabama were again permitted to add the 45 cents a ton to cover increased wages. May 25 the price was reduced 10 cents with all other bituminous districts. The average for the month is indicated at (8).

9. Changes in price of Alabama coal effected by the order of August 22, 1918, are indicated at (9).

TABLES OF PRICES AND RELATIVE PRICES.

ANTHRACITE.

The production of Pennsylvania anthracite represents only 15 per cent of the total coal output of the United States, but the industry is so centralized, both geographically and commercially, so large a portion of the product goes to one class of consumers, the householders, and the factors limiting production are so different from those affecting bituminous coal that the industry is in a separate class from the bituminous-coal industry and must be discussed separately.

The upper limit of production is not at all times the demand, because the larger companies have facilities for storing more than 10 per cent of the total annual output during periods of slack demand. The upper limit of demand is established by the domestic user, for the prepared or domestic sizes of anthracite represent 60 per cent of the total output and the profit-producing part of the business. The history of the production of anthracite is represented by the increase in population of the United States, whereas that of bituminous coal follows the rise and fall of industry.

The prices of the domestic sizes of anthracite are, to a large extent, established by the circular prices of the larger of the high-cost producing companies. The prices of the steam sizes are determined by competition with bituminous coal. Prior to 1916 pea coal was considered a steam size and no summer reductions in its price were offered the trade, as in the prices of the domestic sizes. Beginning with April, 1916, pea coal was classed as a domestic or prepared size and the steam sizes have been buckwheat coal and smaller.

Since 1903 it has been the policy of the anthracite companies to offer a reduction in the price of domestic sizes each summer, beginning with a reduction of 50 cents a gross ton in April, and reaching the full price in September by 10 cent increases each month. This policy has been adopted to encourage the purchase and storage of anthracite by the householder and has been of great benefit to the industry because it has permitted more uniform operation of the mines. These summer reductions in price to the consumer are not accompanied by corresponding decrease in wages to the mine labor. Although it is probable that the loss or lessening of profit on summer sales is offset by greater profits on winter sales, it is fair to assume that the average price for the year, as a result of more uniform and regular operation of the mines, is less than it would be if only such anthracite were produced as was consumed month by month.

The steam sizes of anthracite are sold in competition with bituminous coal and are therefore marketed in much the same manner as bituminous coal. The domestic sizes are sold through selling agents and jobbers to retail dealers, who in turn distribute the product to the householder. The contract year for anthracite is the same as for bituminous coal, April to April, but the wage agreements have until recently been made to cover a four-year period instead of a two-year period, like those on bituminous coal. On domestic sizes of anthracite there is not the difference in current quoted prices and contract prices found in the bituminous trade. About 75 per cent of the total output of anthracite is produced by a comparatively few companies, generally designated the "railroad companies," as distinguished from the independents, who produce

the remaining 25 per cent. These larger companies issue regular circulars quoting prices, which are generally adhered to by them; the independents sell above or below the circular prices, according to the state of the market.

Current quotations of both company and independent coal from January 1, 1913, to September 1, 1917, on the several sizes of anthracite described separately in this report[1] were taken from the trade paper Coal Age. Prices fixed by the President September 1, 1917, and subsequently modified by the Fuel Administrator were used from September 1, 1917, to December, 1918. About 5,000 quotations were thus abstracted, tabulated, and reduced to monthly averages in the same general manner as the bituminous prices. (See pp. 20–21.)

Because Pennsylvania anthracite is invariably sold at the mines by the gross ton (2,240 pounds) the prices are given in the tables in that unit. Many of the quotations obtained were prices for coal delivered, as, for instance, at New York harbor points, and it was necessary to subtract from each such quotation the prevailing freight rate.[2]

To combine the quotations for company and independent coal the figures were averaged, the price for company coal being given three times the weight of the price for the independent coal.

The tables of average prices realized were calculated from the current circular prices reduced to harmonize with the actual annual average realization prices, by sizes, as reported to the Geological Survey.

The diagrams show relative prices of anthracite calculated in the same manner as for bituminous coal. (See pp. 20–21.)

PRICES.

The diagrams and tables on succeeding pages present the data on prices of Pennsylvania anthracite. It will at once be noted that there is an important difference in the general appearance of the curves for the two classes of coal. Prices of anthracite as a whole, compared with the pre-war level, did not advance to so great an extent as prices of bituminous coal. Prices of steam sizes of anthracite, however, recorded a more marked rise than prices of bituminous coal as a whole, but less than prices of central Pennsylvania coal, with which anthracite enters into competition on the Atlantic seaboard. The prices of domestic sizes in 1913, 1914, and 1915 exhibited the summer reduction, greatest in April. Prices were advanced April 1, 1916 (after a wage advance), and the summer reductions for that year do not appear as depressions in the curve but as a low point for the year. From April the prices of the domestic sizes advanced steadily to a maximum for the year in November, 1916, owing to continued heavy demand supplemented in October and November by cold weather. After reaching the high point in November, 1916, prices of domestic sizes, including pea, declined, with lessening demand and warmer weather, to a low point in April, 1917.

[1] Egg, stove, chestnut, pea, and the steam sizes represent 95 per cent of the total commercial production. See current reports on the production of coal in the reports of the United States Geological Survey on mineral resources of the United States.

[2] The necessary records of freight rates were obtained through the courtesy of Mr. E. W. Parker, director of the Anthracite Bureau of Information.

The rate of production of anthracite is shown graphically by the monthly shipments as reported by the Anthracite Bureau of Information in figure 36.

The high prices for domestic sizes of anthracite in the winter of 1916–17 aroused so much interest in the consuming public that Congress directed the Federal Trade Commission to investigate conditions, and that body, though without legal authority to fix prices, laid so firm a restraining hand upon the industry as a whole, to and including the retail dealer, that prices were well under control in the summer of 1917 and did not rise as they had the preceding year and as the prices of bituminous coal did. Summer reductions were offered as usual by the larger companies. No prices of anthracite were agreed upon by the Lane-Peabody committee.

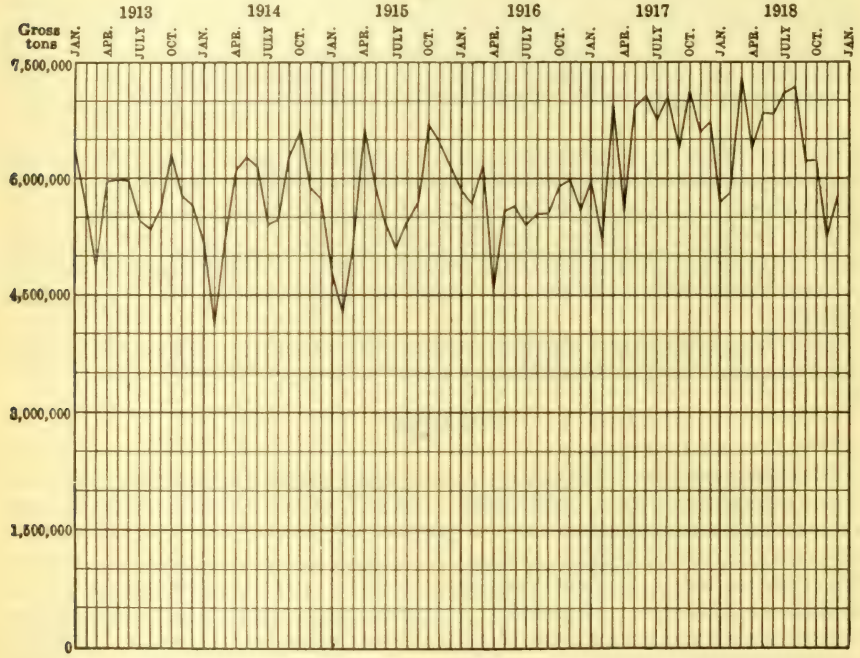

FIGURE 36.—Shipments of Pennsylvania anthracite, by months, 1913–1918.

Prices of anthracite came definitely under the control of the Government on September 1, 1917, when a scale of mine prices was announced by the President. The President's order was in part as follows:

4. Effective September 1, 1917, the maximum prices per ton of 2,240 pounds free on board cars at the mines for the grades and sizes of anthracite coal hereinafter specified shall not exceed the prices indicated in paragraph 5 when such coal is produced and sold by the Philadelphia & Reading Coal & Iron Co., Lehigh Coal & Navigation Co., Lehigh & Wilkes-Barre Coal Co., Hudson Coal Co., Delaware & Hudson Co., Scranton Coal Co., Lehigh Valley Coal Co., Coxe Bros. & Co., Pennsylvania Coal Co., Hillside Coal & Iron Co., Delaware, Lackawanna & Western Railroad Co., Delaware, Lackawanna & Western Coal Co., Susquehanna Coal Co., Susquehanna Collieries Co., Lytle Coal Co., or the M. A. Hanna Coal Co.

5. The grades and sizes for which the maximum prices are specified are as follows: White ash anthracite coal of the grade that between January 1, 1915, and January 1, 1917, was uniformly sold and recognized in the coal trade as coal of white-ash grade;

red ash anthracite coal of the grade that between January 1, 1915, and January 1, 1917, was uniformly sold and recognized in the trade as coal of red-ash grade; and Lykens Valley anthracite coal that is mined exclusively from the Lykens Valley seams and of the grade that between January 1, 1915, and January 1, 1917, was uniformly sold and recognized in the coal trade as coal of Lykens Valley grade.

White-ash grade:	
Broken	$4.55
Egg	4.45
Stove	4.70
Chestnut	4.80
Pea	4.00
Red-ash grade:	
Broken	4.75
Egg	4.65
Stove	4.90
Chestnut	4.90
Pea	4.10
Lykens Valley grade:	
Broken	5.00
Egg	4.90
Stove	5.30
Chestnut	5.30
Pea	4.35

6. Producers of anthracite coal who are not specified in paragraph 4 shall not sell the various grades and sizes of anthracite coal at prices that exceed by more than 75 cents per ton of 2,240 pounds free on board cars at the mines the prices enumerated in paragraph 5: *Provided*, That any producer of anthracite coal who incurs the expense of rescreening it at Atlantic or Lake ports for transshipment by water may increase the price thereof by not more than 5 cents per ton of 2,240 pounds.

7. Producers of anthracite coal specified in paragraph 4 of these regulations shall not sell anthracite coal to producers of anthracite coal not specified in paragraph 4.

8. Dealers and selling agents shall not sell coal produced by the producers included in paragraph 4 on the basis of the prices fixed at the mine for coal produced by producers not specified in said paragraph.

With the exception of the price of pea coal, the prices thus fixed by the President were substantially those in effect at the time. The increase above the market in the price of pea coal as fixed by the President on the advice of the Federal Trade Commission was, on October 1, reduced 60 cents a gross ton at the mine by order of the Fuel Administrator. The prices of anthracite were, on December 1, 1917, advanced by 35 cents a gross ton, after the wage increase authorized by the President.

Summer reductions in the prices of domestic sizes were offered to the trade by the producers in 1918, although not ordered or required by the Fuel Administrator. Instead, however, of a reduction of 50 cents a ton in April, followed by 40 cents in May, and so on, a reduction of 30 cents a gross ton at the mine was offered for five months, April to August, inclusive. This was done to assist in equalizing distribution and to prevent complaints on the part of those who, having ordered in April, would not have been able to procure their coal until later in the summer.

On November 1, 1918, the Fuel Administrator authorized an advance in the maximum price of prepared sizes of Pennsylvania anthracite of $1.05 a gross ton, after an increase in wages granted to the mine laborers in the anthracite regions. On November 15, 1918, a maximum price for steam sizes of anthracite was for the first time fixed by the Government. The maximum price thus established was 50 cents a ton less than that fixed for pea coal.

DIAGRAMS OF RELATIVE PRICES OF ANTHRACITE, 1913–1918.

ALL SIZES.

Figure 38 shows the relative spot prices in this period compared with the average spot prices in the 12 months preceding the war, July, 1913, to June, 1914. Figure 37 shows the relative range in estimated average realization prices from all sales and includes both spot and contract transactions. The spot prices are taken from the New York market quotations of the Coal Age and the average realization prices from annual reports of operators compiled by the Geological Survey. Tables of actual prices and of the computed

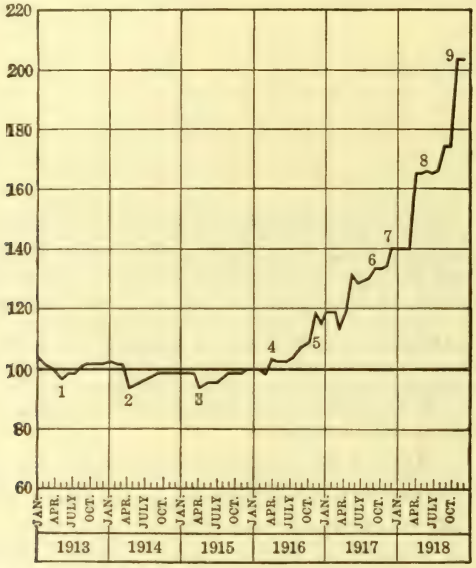

FIGURE 37.—Relative prices realized for Pennsylvania anthracite, all sizes, by months, 1913–1918.

relative prices from which these diagrams were drawn are given on pages 104–111.

1–3. The annual summer reductions in prices of domestic sizes of anthracite for 1913, 1914, and 1915 are shown at these points.

4 and 5. The summer reductions in 1916 were based on an increase in price over the previous year, reached in September and October, 1916 (5).

6. The prices of anthracite were fixed by the President, September 1, 1917 (6). In the period between October, 1916, and September, 1917 (5 and 6), prices of prepared sizes reached a maximum in November, 1916, pea coal a maximum in August, 1917, and steam sizes in June, 1917.

7. An increase of 35 cents a gross ton was allowed by the President, effective December 1, to cover an increase allowed mine labor.

8. The summer reduction of 30 cents, effective April to August, inclusive, offered by the anthracite operators in lieu of the sliding scale of previous years, is shown at (8). A temporary rise in the price of steam sizes in June and an increase again in August, are reflected in the diagram of all sizes, for this period.

9. An increase in price of $1.05 a gross ton, authorized November 7, 1918, and effective November 1, accounts for the sharp rise in the curve at the end of 1918.

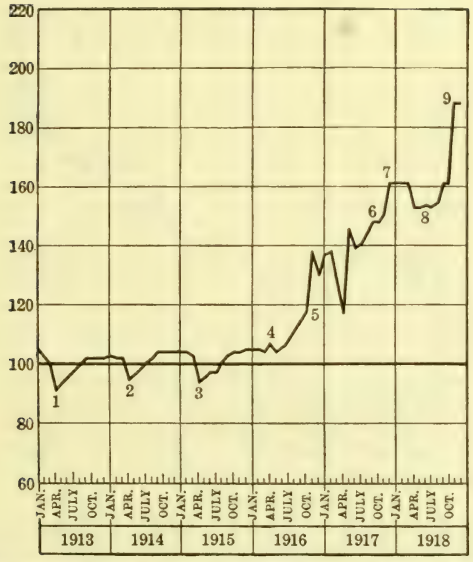

FIGURE 38.—Relative spot prices of Pennsylvania anthracite, all sizes, by months, 1913–1918.

STOVE SIZE.

Figure 40 shows the relative spot prices in this period compared with the average spot prices in the 12 months preceding the war, July, 1913, to June, 1914. Figure 39 shows the relative range in estimated average realization prices from all sales and includes both spot and contract transactions. The spot prices are taken from the New York market quotations of the Coal Age and the average realization prices from annual reports of operators compiled by the Geological Survey. Tables of actual prices and of the computed relative prices from which these diagrams were drawn are given on pages 104–111.

1–3. The annual summer reductions in the price of stove coal in 1913, 1914, and 1915 are shown at these points.

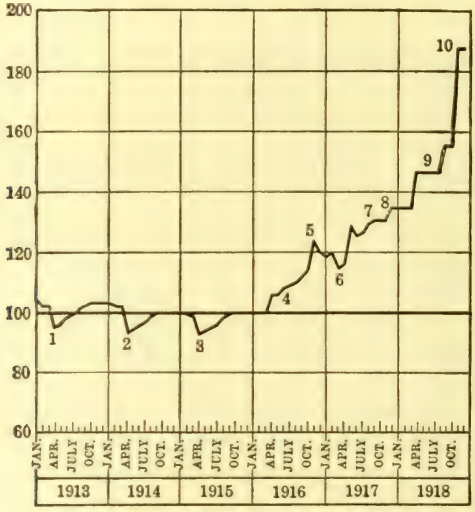

FIGURE 39.—Relative prices realized for Pennsylvania anthracite, stove size, by months, 1913–1918.

4, 5. The summer reductions in 1916 were based on an increase in price over the preceding year and resulted, therefore, in a steady increase in price through the summer to the new level of circular prices for September. The highest price for stove coal in the years 1913–1917 was reached in November, 1916 (5).

6. From the low prices in April, 1917, the advance was rapid until fall.

7. Prices of anthracite were fixed by the President, September 1, 1917 (7).

8. An increase of 35 cents a gross ton was allowed by the President, effective December 1, to cover an increase allowed mine labor.

9. The summer reduction of 30 cents, effective April to August, inclusive, offered by the anthracite operators in lieu of the sliding scale of the previous years, is shown at (9). In the diagram based on spot prices this reduction appears as a sag in the curve. In the diagram based on average realization, the summer reduction in 1918 is preceded by a rise, the extent of which is subject to correction when the actual realization for the year 1918 has been compiled by the Geological Survey from the returns of the operators.

10. An increase in price of $1.05 a gross ton, authorized November 7, 1918, and effective November 1, accounts for the very sharp rise in the curve at the end of 1918.

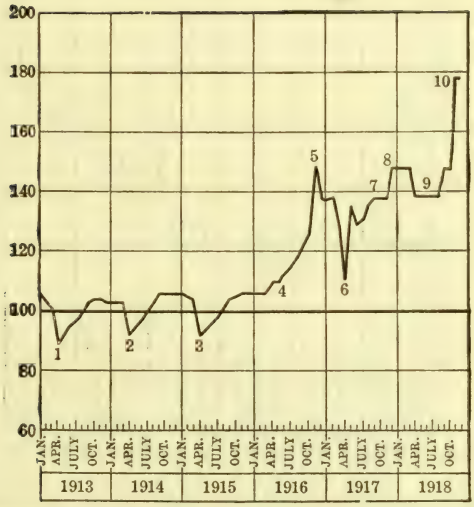

FIGURE 40.—Relative spot prices of Pennsylvania anthracite, stove size, by months, 1913–1918.

EGG SIZE.

Figure 42 shows the relative spot prices in this period compared with the average spot prices in the 12 months preceding the war, July, 1913, to June, 1914. Figure 41 shows the relative range in estimated average realization prices from all sales and includes both spot and contract transactions. The spot prices are taken from the New York market quotations of the Coal Age and the average realization prices from annual reports of operators compiled by the Geological Survey. Tables of actual prices and of the computed relative prices from which these diagrams were drawn are given on pages 104–111.

1–3. The annual summer reductions in the price of egg coal in 1913, 1914, and 1915 are shown at these points.

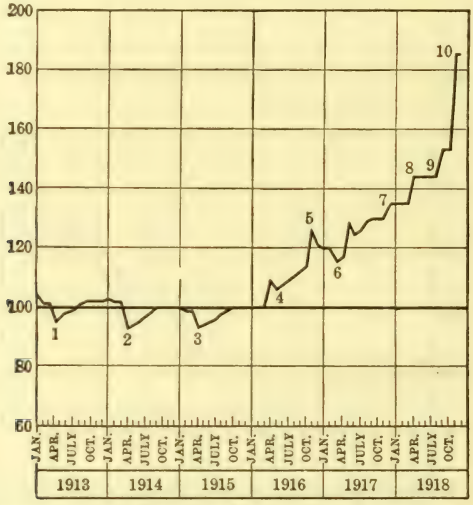

FIGURE 41.—Relative prices realized for Pennsylvania anthracite, egg size, by months, 1913–1918.

4, 5. The summer reductions in 1916 were based on an increase in price over the preceding year and resulted, therefore, in a steady increase in price through the summer to the new level of circular prices for September. The highest price for egg coal in the years 1913–1917 was reached in November, 1916 (5).

6. From the low prices in April, 1917, the advance was rapid until fall.

7. Prices of anthracite were fixed by the President, September 1, 1917 (7).

8. An increase of 35 cents a gross ton was allowed by the President, effective December 1, to cover an increase allowed mine labor.

9. The summer reduction of 30 cents, effective April to August, inclusive, offered by the anthracite operators in lieu of the sliding scale of the previous years, is shown at (9). In the diagram based on spot prices this reduction appears as a sag in the curve. In the diagram based on average realization prices, the summer reduction in 1918 is preceded by a rise, the extent of which is subject to correction when the actual realization for the year 1918 has been compiled by the Geological Survey from the returns of the operators.

10. An increase in price of $1.05 per gross ton, authorized November 7, 1918, and effective November 1, accounts for the very sharp rise in the curve at the end of 1918.

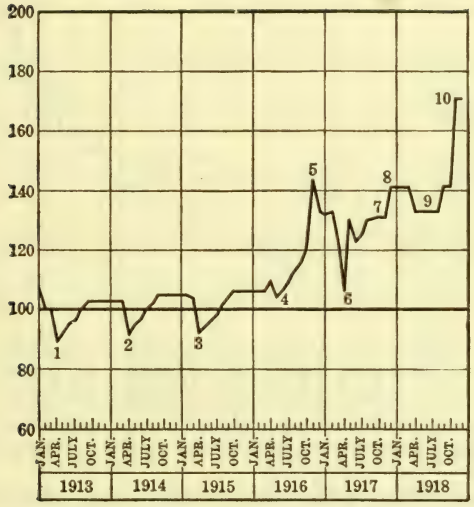

FIGURE 42.—Relative spot prices of Pennsylvania anthracite, egg size, by months, 1913–1918.

CHESTNUT SIZE.

Figure 44 shows the relative spot prices in this period compared with the average spot prices in the 12 months preceding the war, July, 1913, to June, 1914. Figure 43 shows the relative range in estimated average realization prices from all sales and includes both spot and contract transactions. The spot prices are taken from the New York market quotations of the Coal Age and the average realization prices from annual reports of operators compiled by the Geological Survey. Tables of actual prices and of the computed relative prices from which these diagrams were drawn are given on pages 104–111.

1–3. The annual summer reductions in the price of chestnut coal in 1913, 1914, and 1915 are shown at these points.

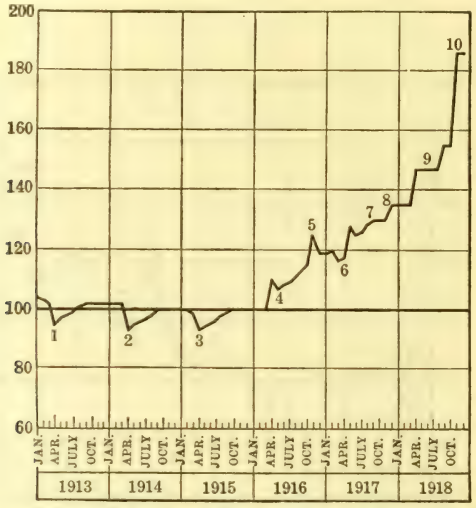

FIGURE 43.—Relative prices realized for Pennsylvania anthracite, chestnut size, by months, 1913–1918.

4, 5. The summer reductions in 1916 were based on an increase in price over the preceding year and resulted, therefore, in a steady increase in price through the summer to the new level of circular prices for September. The highest price for chestnut coal in the years 1913–1916 was reached in November, 1916 (5).

6. From the low prices in April, 1917, the advance was rapid until fall.

7. Prices of anthracite were fixed by the President, September 1, 1917 (7).

8. An increase of 35 cents a gross ton was allowed by the President, effective December 1, to cover an increase allowed mine labor.

9. The summer reduction of 30 cents, effective April to August, inclusive, offered by the anthracite operators in lieu of the sliding scale of the previous years, is shown at (9). In the diagram based on spot prices this reduction appears as a sag in the curve. In the diagram based on average realization prices the summer reduction in 1918 is preceded by a rise, the extent of which is subject to correction when the actual realization for the year 1918 has been compiled by the Geological Survey from the returns of the operators.

10. An increase in price of $1.05 per gross ton, authorized November 7, 1918, and effective November 1, accounts for the very sharp rise in the curve at the end of 1918.

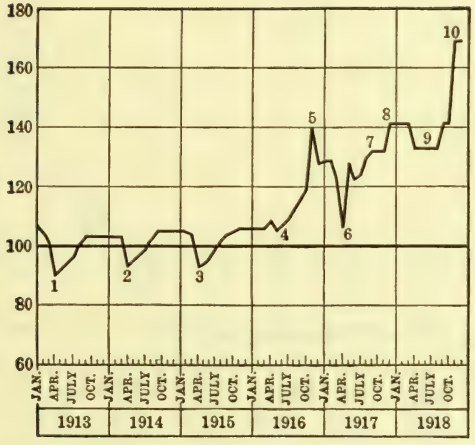

FIGURE 44.—Relative spot prices of Pennsylvania anthracite, chestnut size, by months, 1913-1918.

PEA SIZE.

Figure 46 shows the relative spot prices in this period compared with the average spot prices in the 12 months preceding the war, July, 1913, to June, 1914. Figure 45 shows the relative range in estimated average realization prices from all sales and includes both spot and contract transactions. The spot prices are taken from the New York market quotations of the Coal Age and the average realization prices from annual reports of operators compiled by the Geological Survey. Tables of actual prices and of the computed relative prices from which these diagrams were drawn are given on pages 104–111.

1, 2. In the period from 1913 to 1916 the status of pea coal changed from a steam size to a domestic size because of the greatly increased use of this size in household

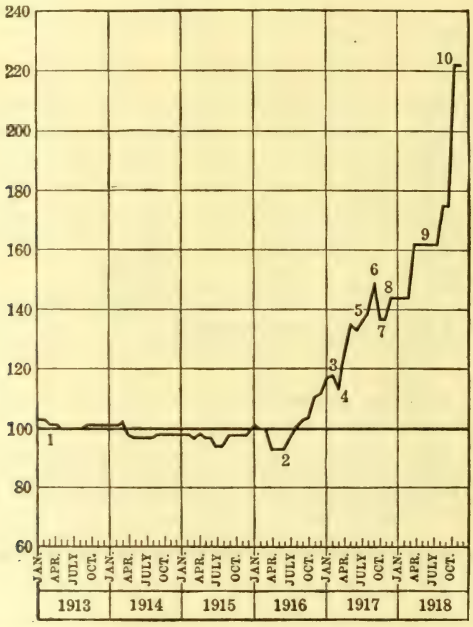

FIGURE 45.—Relative prices realized for Pennsylvania anthracite, pea size, by months, 1913–1918.

heating. In 1915 and 1916 pea coal was known as "poor man's anthracite," and until the middle of 1916 there was relatively little increase in its price. In 1916, for the first time, pea coal was formally recognized as a domestic size by its inclusion, with the other domestic sizes, in the summer scale of prices.

3. From the middle of 1916 the price of pea coal steadily advanced at a rate more than double that of the other prepared sizes. The maximum for the winter of 1916–17 was reached in February of 1917 (3).

4, 5. The prices declined in April, but began to increase in May and in August reached a new high level (5).

6, 7. The prices of pea coal were fixed by the President, September 1, 1917 (6). The price of pea coal announced on that date was about 60 cents per ton above the prevailing market price in August and accordingly, on October 1, the Fuel Administrator reduced the price by that amount (7).

8. An increase of 35 cents a gross ton was allowed by the President, effective December 1, to cover an increase allowed mine labor.

9. The summer reduction of 30 cents, effective April to August, inclusive, offered by the anthracite operators in lieu of the sliding scale of the previous years, is shown at (9). In the diagram based on spot prices this reduction appears as a sag in the curve. In the diagram based on average realization prices, the summer reduction in 1918

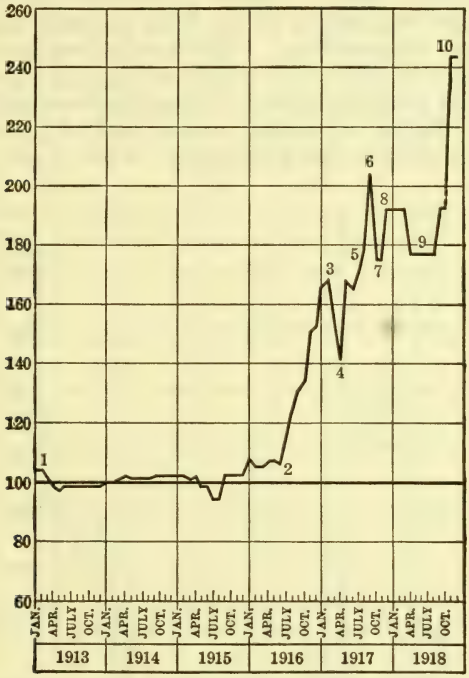

FIGURE 46.—Relative spot prices of Pennsylvania anthracite, pea size, by months, 1913–1918.

is preceded by a rise, the extent of which is subject to correction when the actual realization for the year 1918 has been compiled by the Geological Survey from the returns of the operators.

10. An increase in price of $1.05 a gross ton, authorized November 7, 1918, and effective November 1, accounts for the sharp rise in the curve at the end of 1918.

STEAM SIZES.

Figure 48 shows the relative spot prices in this period compared with the average spot prices in the 12 months preceding the war, July, 1913, to June, 1914. Figure 47 shows the relative range in estimated average realization prices from all sales and includes both spot and contract transactions. The spot prices are taken from the New York market quotations of the Coal Age and the average realization prices from annual reports of operators compiled by the Geological Survey. Tables of actual prices and of the computed relative prices from which these diagrams were drawn are given on pages 104–111.

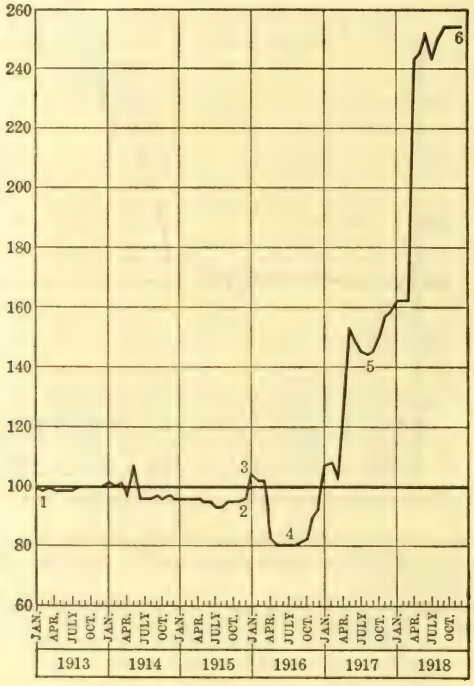

FIGURE 47.—Relative prices realized for Pennsylvania anthracite, steam sizes, by months, 1913–1918.

1–3. The prices of steam sizes followed very closely the prices of bituminous coal, with which they enter into competition. The diagrams for steam sizes will thus be found to resemble those for bituminous coals from central Pennsylvania (pp. ———). Spot prices did not vary greatly in 1913, 1914, and 1915, but there was a steady drop in the three years in the average realization prices. The sharp rise in prices in the eastern bituminous fields in the winter of 1915–16 is found also in prices of steam sizes of anthracite (3).

4, 5. The depressions in the curves representing drop in prices in the summer of 1916 were similar to those of bituminous coal, but were of greater extent. From the fall of 1916 until the end of 1918 the prices of steam sizes steadily advanced, with two recessions—a slight one in the early part of 1917 and another, more marked, in the fall of 1917 (5), when prices of bituminous coal were fixed at a lower level by the President.

6. Effective November 16, 1918, the prices of steam sizes were for the first time fixed by the Government, the maximum price established having been 50 cents under the price of pea coal in effect at the time.

FIGURE 48.—Relative spot prices of Pennsylvania anthracite, steam sizes, by months, 1913–1918.

TABLES OF PRICES AND RELATIVE PRICES OF ANTHRACITE COAL.

Spot prices of anthracite coal f. o. b. mines, 1913–1918.

[Unit, gross tons of 2,240 pounds.]

	Anthracite coal.

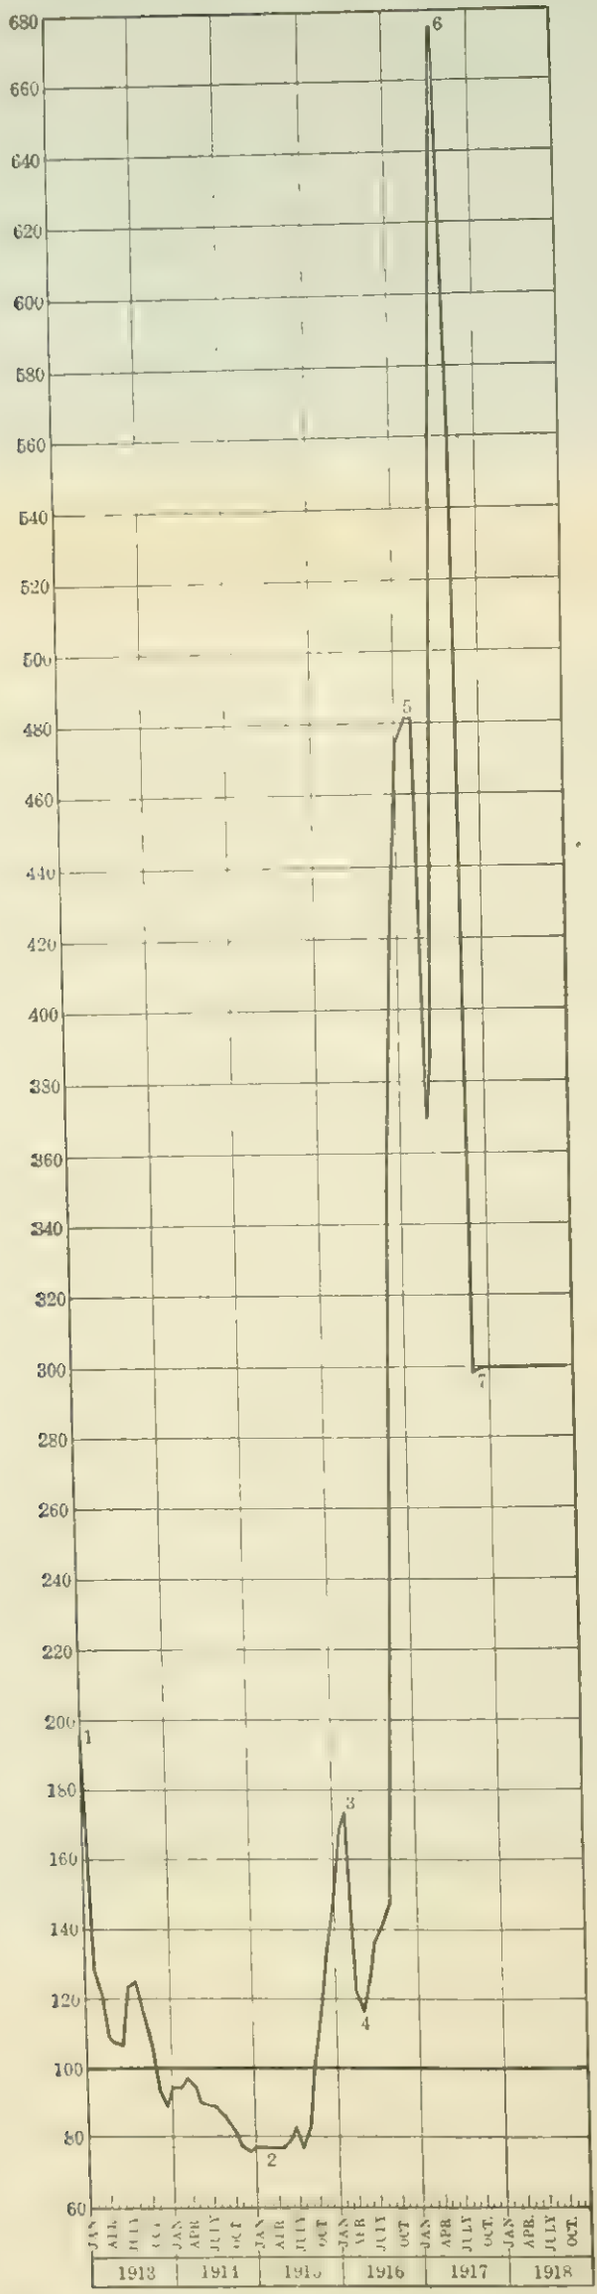
COKE.

Prices of beehive coke are presented for two producing districts, Connellsville, Pa., and Birmingham, Ala. The spot prices of beehive coke from the Connellsville district were taken from the Iron Age. The prices for furnace and foundry coke were averaged in accordance with the relative production of each in 1916, as reported to the Geological Survey by the producers. The average realized prices were computed from the spot quotations and the average annual realization prices were reported by the Geological Survey, in the same manner as for bituminous prices (see pp. 20–21), except that the assumption was made that 10 per cent of the total output was sold on the market and 90 per cent under contract and that the "coke year" was from January to December.

The quotations on Birmingham coke were also taken from the Iron Age, with due regard in combining the prices of furnace and foundry coke to the relative quantities of the two grades produced. The average prices realized were computed as for Connellsville coke. The weighted average prices for the period in which prices were fixed by the Fuel Administrator were determined from the data of the Coke Section of the Fuel Administration used in fixing the prices for the various operations. These data showed for 1917 the production of both furnace and foundry coke by individual plants and the prices fixed for each.

The range of prices for beehive coke in 1913–1918 exhibits the same tendencies as that for bituminous coal. From a high point in 1913 prices, with minor fluctuations, declined through 1914 to a low point in the middle of 1915. A temporary rise in the winter of 1915–16 was followed by a decline in the summer of 1916 and a sharp rise in the winter of 1916–17, which continued to a maximum in the summer of 1917. Government control of prices was first exercised through the War Industries Board in an order issued September 23, 1917, fixing prices on iron and steel products. This order established the price of coke as $6 a ton at the ovens, "Connellsville base." Subsequent orders of the Fuel Administrator interpreted this general order and fixed the price of coke, both beehive and by-product, at the plants and in the districts on the basis of cost of production. It is worthy of note that the Government prices in effect at the end of 1918, for both Connellsville and Birmingham coke, represent approximately the same increase over the average realization prices in the pre-war period.



RELATIVE SPOT PRICES OF COKE PRODUCED IN THE CONNELLSVILLE DISTRICT, PA., BY MONTHS, 1913-1918

DIAGRAMS OF RELATIVE PRICES OF COKE, 1913-1918.

CONNELLSVILLE COKE.

Plate I shows the relative prices in this period compared with the average spot prices in the 12 months preceding the war, July, 1913, to June, 1914. Figure 49 shows the relative range in estimated average realization prices from all sales, and includes both spot and contract transactions. The spot prices are taken from the Connellsville, Pa., market quotations of the Iron Age and the average realization prices from annual reports of operators compiled by the Geologi-

FIGURE 49.—Relative prices realized for coke produced in the Connellsville district, Pa., by months, 1913–1918.

cal Survey. Tables of actual prices and of the computed relative prices from which these diagrams were drawn are given on pages 85–87.

1–4. From $2.95 in January, 1913 (1), the spot price of Connellsville coke declined to $1.52 (2) in the first half of 1915. Beginning in September, 1915, the spot price rose to $3.48 in March, 1916 (3), but declined to $2.33 in May (4).

5. From June, 1916, to February and March, 1917 (5), spot prices rose to $9.66, but declined to $7.43 in April.

6. The maximum spot price for the six-year period was reached in August, 1917 (6), at $13.59.

7. From the peak in August, spot prices declined to $6, the Government price, in October (7).

137536°—M R 1918—PT 2——8

BIRMINGHAM COKE.

Figure 51 shows the relative spot prices in this period compared with the average spot prices in the 12 months preceding the war, July, 1913, to June, 1914. Figure 50 shows the relative range in estimated average realization prices from all sales and includes both spot and contract transactions. The spot prices are taken from the Birmingham market quotations of the Iron Age and the average realization

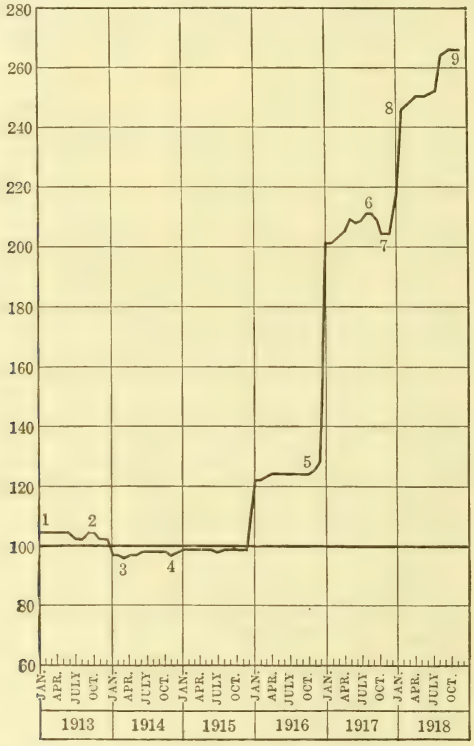


FIGURE 50.—Relative prices realized for coke produced in the Birmingham district, Ala., by months. 1913–1918.

prices from annual reports of operators compiled by the Geological Survey. Tables of actual prices and of the computed relative prices from which these diagrams were drawn are given on pages 85–87.

1–5. Spot prices of Alabama coke ranged from $3.34 in the first part of 1913 (1) and a maximum of $3.15 for the years 1913–1915 in September, 1914 (2), to a minimum of $2.57 in March, 1914 (3). The minimum spot price in 1915 was $2.65 in July (4), from which the price rose steadily to $3.49 in September, 1916 (5).

6. The market price for Alabama coke rose rapidly from November, 1917, to a maximum of $8.27 in August and September, 1917 (6).

7. Prices fixed by the Government in November are shown at (7).

8. Substantial increases in the prices of coke allowed by the Fuel Administrator in the Black Creek, Brookwood, and Blue Creek districts on January 29, 1918, and in other portions of the field on February 15, raised the general average in February from $6.06 to $6.92 (8).

9. Subsequent changes in prices of Alabama coke allowed by the Fuel Administrator raised the general average by the end of 1918 to $7.46 (9).

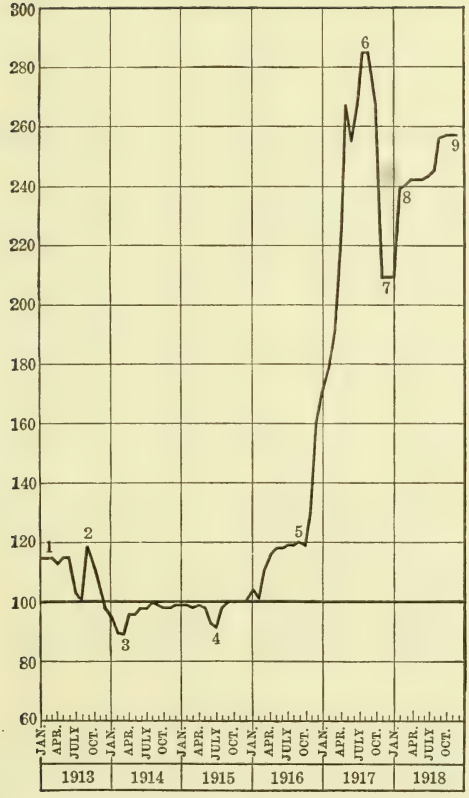

FIGURE 51.—Relative spot prices of coke produced in the Birmingham district, Ala., by months, 1913–1918.

SALT, BROMINE, AND CALCIUM CHLORIDE.

By R. W. Stone.[1]

SALT.

PRODUCTION AND TRADE CONDITIONS.

The quantity of salt produced and sold in the United States in 1918 was 7,238,744 short tons, valued at $26,940,361, an increase of 3.7 per cent in quantity and 35.1 per cent in value over the production in 1917.

The values given in the tables in this report do not include the value of cooperage or containers.

Salt produced and marketed in the United States, 1913–1918.

Year.	Quantity.				Total value.	Average price per ton.
	Manufactured (evaporated) (short tons).	In brine (short tons).	Rock salt (short tons).	Total (short tons).		
1913	2,131,229	1,622,382	1,062,291	4,815,902	$10,123,139	$2.10
1914	2,159,094	1,652,758	1,060,804	4,872,656	10,197,417	2.09
1915	2,335,823	1,851,199	1,165,387	5,352,409	11,747,686	2.19
1916	2,454,836	2,539,717	1,368,353	6,362,906	13,645,947	2.14
1917	2,482,564	2,890,588	1,605,025	6,978,177	19,940,442	2.86
1918	2,724,203	2,830,600	1,683,941	7,238,744	26,940,361	3.72

The figures in this table show that the increase in the production of manufactured or evaporated salt in 1918 as compared with 1917 was 9.7 per cent and of rock salt 4.9 per cent. The production of brine salt decreased 2 per cent. The average price of all salt produced increased 30 per cent and was $3.72 a ton in 1918 as compared with $2.86 in 1917. This increase in price is a little less than the increase in 1917, which was 33 per cent, but was caused by the same things—higher wages and higher cost of fuel and other supplies.

There was a distinct shortage of labor in some localities in 1918, and the closing of factories on Mondays by the Fuel Administration for a few weeks early in the year caused some reduction in the quantity of salt produced. In general the demand for salt was good, orders being easily obtained, but the high and rapidly increasing cost of materials and the difficulty of getting help made it hard for some

[1] The statistical part of this report is the work of Miss M. S. Lundborg for domestic material and of J. A. Dorsey for imports and exports.

producers to fill their orders. Producers in New York reported labor high and scarce and costs greatly increased but an advance in price disproportionately low. In Michigan one operator reported no change from 1917 in operating expense but others reported the cost of operation increased from 50 to 60 per cent. One operator in Kansas reported the cost about double that in 1916, except overhead charges, which had increased 25 per cent, and one producer in Texas reported the cost of fuel, labor, and containers as advanced much more than the prices received for salt. The Utah producers agreed that the demand was about the same as in 1917 and the prices remained practically stationary, but the cost of operating increased from 30 to 75 per cent. California producers reported the cost of labor practically double that of 1917, and one operator stated that it was impossible to get labor at any price. In the San Diego district the cost of producing increased according to one producer 25 to 30 per cent and according to another, 50 per cent, and prices increased in proportion. In the San Francisco Bay district there was some loss of salt on account of the heavy rain on September 12, which diluted the pickle and resulted in a considerable injury or loss to the crop. It is the general opinion that the cost of sacks in California increased about 300 per cent and that this was one of the principal reasons for the rise in prices. One producer stated that although the prices were raised considerably the profits were less than formerly. In Porto Rico one operator reported the market dull from lack of shipping and an increase of about 50 per cent in cost of labor and of 300 per cent in cost of packing, but the selling price of the salt remained unchanged.

The Morris Co., at Little River, Rice County, Kans., reported its plant completed and the shipment of salt begun on September 23, 1918. Benners Salt Co. (Inc.), New Orleans, La., reported its plant at Anse la Butte, St. Martin Parish, in course of construction and the expectation to have the product on the market by the summer of 1919. The Roessler & Hasslacher Chemical Co reported production for the first time from a plant at St. Albans, Kanawha Country, W. Va.

PRODUCTION BY STATES.

In 1918 the leading States in total quantity of salt produced were Michigan, New York, and Ohio. The number of operating plants in the principal States was California 22, Michigan 25, New York 17, Kansas 11, Ohio 12, and other States from 1 to 5 each, a total of 102 plants as compared with 125 plants in 1917.

Salt produced and marketed in the United States, 1915–1918.

ROCK SALT.

Large quantities of rock salt are mined in New York, Michigan, Kansas, and Louisiana from beds several hundred feet below the surface. In the arid regions of the West rock salt is taken from deposits at or near the surface. Idaho, Nevada, Utah, and California produce small quantities of this salt. Large quantities are available in these States, but there is little demand.

Rock salt produced and marketed in the United States,[a] 1914–1918.

Year.	Quantity (short tons).	Value.	Average price per ton.
1914	1,060,804	$2,024,898	$1.91
1915	1,165,387	2,299,894	1.97
1916	1,368,353	2,665,270	1.95
1917	1,605,025	3,897,595	2.43
1918	1,683,941	5,684,661	3.38

a California, Kansas, Louisiana, Michigan, New York, and Utah; in 1916 Idaho also; in 1917 Nevada also; in 1918 Idaho and Nevada also.

This table shows an increase in 1918 of 4.9 per cent in quantity and 45.8 per cent in value over the production of 1917, as compared with an increase of 17.3 per cent in quantity and 46.2 per cent in value in 1917 over the production of 1916.

New York is by far the largest producer of rock salt, its output being more than double that of Kansas, the next largest producer. Louisiana comes third and Michigan fourth, but the production of these two States was only a little more in 1918 than the output of Kansas. It is not possible to publish State totals for rock salt without revealing individual output, because in most States there are only one or two producers. Rock salt is mined by 19 producers in 8 States.

BRINE SALT.

The various grades of salt produced by evaporating natural and artificial brine are put on the market under different names, according to use, size of grain, or method of preparation.

Brine salt produced and marketed in the United States, 1914–1918.

Year.	Table and dairy.		Packers' salt.			
			Common fine.		Common coarse.	
	Quantity (short tons).	Value.	Quantity (short tons).	Value.	Quantity (short tons).	Value.
1914	577,020	$3,221,007	873,301	$2,383,588	530,483	$1,453,484
1915	607,749	3,720,020	981,829	2,762,450	536,774	1,724,503
1916	654,601	4,326,531	1,048,032	3,314,795	567,985	1,958,094
1917	688,022	5,908,788	1,048,572	5,311,668	493,515	2,659,013
1918	804,482	7,336,667	1,072,331	7,024,631	541,329	3,689,807

Year.	Coarse solar.		Pressed blocks and other grades.		In brine.		Total.	
	Quantity (short tons).	Value.	Quantity (short tons).	Value.	Quantity (short tons)	Value.	Quantity (short tons)	Value.
1914	151,228	$451,206	27,062	$73,715	1,652,758	$589,519	3,811,852	$8,172,519
1915	162,569	508,402	46,902	130,452	1,851,199	601,965	4,187,022	9,447,792
1916	116,913	339,079	67,305	210,337	2,539,717	831,841	4,994,553	10,980,677
1917	159,361	524,987	93,094	554,805	2,890,588	1,083,586	5,373,152	16,042,847
1918	191,260	903,669	114,801	1,055,661	2,830,600	1,245,265	5,554,803	21,255,700

From the preceding table the following percentages have been determined:

Increase or decrease in brine salt produced in 1918 compared with 1917.

	Quantity (per cent).	Value (per cent).
Table and dairy	+16.9	+24.2
Common fine	+ 2.2	+32.2
Common coarse	+ 9.7	+38.7
Coarse solar	+20.0	+71.9
Pressed blocks, etc	+23.3	+90.4
Brine	− 2.1	+14.9

The only decrease in production was in the salt in brine, which fell off 2.1 per cent in quantity but increased 14.9 per cent in value. It is particularly conspicuous that the increases in value are very much larger than the increases in quantity. The increase of 20 per cent in quantity of solar salt produced indicates that in general weather conditions were favorable for solar evaporation. The demand for pressed blocks for salting cattle is increasing. The total quantity produced was 94,150 tons, valued at $939,900. This gives an average value per ton of $9.98. Kansas was by far the largest producer, with an output of 55,611 tons, valued at $498,099, as compared with Michigan, the second largest producer, which made an output of 19,362 tons, valued

at $192,376. The other States producing pressed block are, in order of quantity produced, Texas, Utah, Ohio, and California. Salt not classified and included in "other grades" amounted to 20,651 tons, valued at $115,761.

The quantity and value of salt in brine used by chemical works showed for the first time in a number of years a decrease in the quantity used. The products made by chemical companies from nearly 3,000,000 tons of brine salt include salt cake, soda ash, caustic soda, sodium carbonate, sodium acetate, sodium chlorate, sodium phosphate, sodium silicate, sal soda, Glauber's salt, calcium chloride, chlorine, and hydrochloric acid.

Without including the salt in brine sold as such or used by chemical works, the evaporated salt was produced in the States and in the quantities shown in the following table:

Evaporated salt produced and marketed in the United States in 1917 and 1918.

State.	1917		1918	
	Quantity (short tons).	Value.	Quantity (short tons).	Value.
California	192,565	$902,753	202,607	$1,154,852
Kansas	299,877	1,449,442	347,255	2,665,330
Michigan	891,195	5,859,594	1,059,872	7,926,745
Nevada	(a)	(a)	545	2,900
New York	517,273	3,077,910	521,568	3,871,887
Ohio	386,803	2,527,432	389,887	2,773,390
Texas	85,181	564,029	79,657	762,006
Utah	73,282	337,102	88,067	558,838
West Virginia	24,844	191,044	26,077	251,668
Other States b	11,544	49,955	8,668	42,819
	2,482,564	14,959,261	2,724,203	20,010,435
Percentage of increase in 1918			9.6	33.7

a Included in "Other States."
b Hawaii, Idaho, New Mexico, Oklahoma, and Porto Rico in 1918, with the addition of Pennsylvania in 1917.

AVERAGE PRICE.

The average price per ton of all grades of salt produced and marketed in the United States, as shown in the table on page 117, advanced from $2.86 in 1917 to $3.72 in 1918. Rock salt commonly is cheaper than evaporated or brine salt, and the price of each differs in different localities by reason of a variety of factors, among which supply and demand are potent. The following table shows some anomalous variations in price from year to year in certain States, but a general tendency toward higher prices is noticeable, especially in the last two years, and is most apparent in the averages given at the bottom of the table. The averages for the United States are computed from the quantity and value of the entire production for the year indicated and not from the State averages in the respective columns above them.

Average price per ton of domestic salt, 1914–1918.

State.	Rock salt.					Brine salt.				
	1914	1915	1916	1917	1918	1914	1915	1916	1917	1918
California	$7.00	$3.98	$2.99	$4.21	$5.50	$5.08	$4.73	$4.20	$4.34	$5.69
Hawaii							8.00	7.00	15.00	18.00
Idaho			10.00	10.00	10.00	12.38	10.00	15.00	15.60	18.00
Kansas	1.29	1.34	1.35	1.66	2.53	3.24	2.55	2.61	3.63	5.91
Louisiana	2.29	2.52	2.28	3.37	3.67					
Michigan	2.56	2.02	2.60	2.92	3.63	1.99	2.43	2.18	3.06	3.78
Nevada				3.00	3.00	3.94	4.07	4.35	3.18	5.32
New Mexico						7.00	2.76	2.00	2.41	10.00
New York	1.91	1.95	1.98	2.41	3.59	1.96	1.86	1.81	2.52	3.33
Ohio						1.72	1.78	2.17	2.77	3.00
Oklahoma						3.69	6.91	6.22	6.61	4.74
Pennsylvania						5.25			3.00	
Porto Rico						2.89	2.57	2.62	4.24	4.00
Texas						5.36	5.55	5.46	6.62	9.56
Utah	2.81	2.29	2.24	2.54	3.50	4.61	5.04	4.99	4.60	6.35
West Virginia						3.83	3.54	3.67	7.69	9.65
Average for the United States	1.91	1.97	1.95	2.43	3.38	2.14	2.26	2.62	2.99	3.83

From this table it is determined that the average price per ton of rock salt, $3.38 in 1918, increased 39.1 per cent over the average price for 1917, as compared with an increase of 24.6 per cent in that year over 1916. Likewise the average price per ton of brine salt, $3.83 in 1918, was an increase of 28.1 per cent over the average price in 1917, as compared with an increase of 14.1 per cent in that year over 1916.

DOMESTIC CONSUMPTION.

On the assumption that the population of the United States is 100,000,000, the quantity of salt used in this country in 1918 amounted to about 143 pounds, or a little more than half a barrel, per capita. The following table shows that very nearly all the salt used in the United States in 1918 was of domestic origin and that the percentage of imports to domestic consumption was less than ever before. Part of our domestic production was exported, but the exports were partly offset by imports, which were 0.6 per cent of the total consumption.

Supply of salt for domestic consumption, 1900–1918, in short tons.

Source.	1900	1910	1915	1916	1917	1918

IMPORTS.

According to figures obtained from the Bureau of Foreign and Domestic Commerce, Department of Commerce, and after conversion from pounds as reported by that bureau to short tons, the salt imported and entered for consumption in the United States in the last five years is as follows:

Salt imported and entered for consumption in the United States, 1914–1918.

Year.	In bags, barrels, and other packages.		In bulk.		Total quantity (short tons).	Total value.
	Quantity (short tons).	Value.	Quantity (short tons).	Value.		
1914	32,807	$212,349	97,997	$168,454	130,804	$380,803
1915	28,724	196,593	93,602	169,859	122,326	366,452
1916	24,402	200,290	97,677	142,298	122,079	342,588
1917	13,472	139,339	51,450	140,796	64,922	280,135
1918	10,259	148,128	30,031	133,340	40,290	281,468

The source of the imported salt is shown in the following table:

Salt imported into the United States, 1916–1918.

[General imports.]

Country.	1916		1917		1918	
	Quantity (pounds).	Value.	Quantity (pounds).	Value.	Quantity (pounds).	Value.
Germany						
Italy	11,456,800	$8,028				
Portugal			3,724,600	$7,651	112,000	$216
Spain	68,740,200	35,243	7,342,000	5,209	10,180,000	6,750

Barbados	140,000	140				
Trinidad and Tobago						
Other British West Indies	81,388,200	55,257	65,859,900	72,621	25,779,400	35,815
Cuba					103,800	134
Dutch West Indies	5,748,900	5,865	13,102,900	10,459	4,731,400	8,779
French West Indies					200,000	425
Dominican Republic					3,858,000	4,824
China			15,200	14		
Japan					200	5
Hongkong	200	6				
Portuguese Africa	237,400	170			896,000	800
	243,933,900	342,588	131,680,000	280,135	80,629,200	284,032

A large part of the imported salt is coarse solar salt made by evaporating sea water and comes from the West Indies and Spain. This cheap material enters the United States at a low freight rate and is used largely for curing fish and meats. The importation of salt from England is largely to supply packers who think they can not get satisfactory results without Liverpool salt.

The slight discrepancy between the number of pounds imported as shown in this table and the number of tons in the second table above is explained by the fact that some of the salt imported was in warehouse at the close of the year and had not been entered for consumption.

EXPORTS.

The exports of salt in 1918 were 20 per cent greater in quantity and more than 67 per cent greater in value than in 1917. They were greater than ever before and were sent to all parts of the world. The accompanying tables were made from figures obtained from the Bureau of Foreign and Domestic Commerce.

Salt of domestic production exported from the United States, 1914–1918.

Year.	Quantity.		Value.
	Pounds.	Equivalent in short tons.	
1914	164,589,012	82,295	$586,055
1915	160,948,077	80,474	613,847
1916	168,129,201	84,065	567,441
1917	227,985,222	113,993	1,000,773
1918	273,565,496	136,783	1,677,577

According to the preceding table more than one-half of the salt exported from the United States goes to Canada. The quantity sent to Canada is increasing steadily and the 160,360,923 pounds, or 80,180 short tons, exported to Canada in 1918 was more than double the quantity exported in 1915. Cuba is the next largest consumer, having taken 58,498,163 pounds, or about 29,250 short tons, in 1918. The most notable increase among the larger importers of salt from the United States is New Zealand, which took 720 tons in 1916 and 11,465 tons in 1918. Mexico and Panama were the next largest consumers of United States salt in 1918. South American countries took comparatively little, they being supplied more largely from England.

DOMESTIC DEPOSITS.

The salt deposits in the United States are fully described in United States Geological Survey Bulletin 669, "The salt resources of the United States," by W. C. Phalen. This illustrated bulletin of 285 pages was issued in May, 1919, and may be obtained free of charge on application to the Director, United States Geological Survey, Washington, D. C. It contains descriptions of the deposits, arranged by States, a discussion of the origin and formation of saline deposits, many analyses of rock salt, brines, and bitterns, and statistics of the production of salt since the beginning of the industry.

FOREIGN DEPOSITS.

In view of the recent need for information on the mineral resources of other countries, the following summary of distribution of salt throughout the world has been prepared.

NORTH AMERICA.

Canada.—In Canada practically the only producing Province is Ontario. Along the eastern shore of Lake Huron are rock salt beds about 1,000 feet below the surface and 14 to 252 feet thick. Salt is recovered by drilling wells and filling them with water, thus dissolving the salt, which is pumped up in the form of brine, and then evaporated and prepared for market.

Canada produced 131,727 tons of salt in 1918 and imported about 80,180 tons from the United States as well as a considerable quantity from England. About 300 tons of salt was shipped from Canada to the United States in 1918, a great decrease from the 8,000 to 10,000 formerly shipped annually to this country.

A deposit of rock salt is being developed neat Malagooh, Cumberland County, Nova Scotia. This is the first rock salt discovered in Canada that can be reached by a shaft of moderate depth.

Mexico.—High-grade salt for table use in Mexico is mostly imported from the United States and England. Exports to Mexico from this country have ranged in the last five years from 2,200 to 7,500 tons in a year. Domestic production supplies a large part of the salt consumed but much of the domestic material is not refined. It is derived in large part from the solar evaporation of sea water and to a less extent from mines.

Central America.—Only a small quantity of salt is made in the countries of Central America, much of the demand being supplied by importation from England and the United States. Exports to these countries from the United States amount to 3,000 to 4,000 tons annually, most of which goes to Panama. Most of the native salt is made by solar evaporation of sea water along the Pacific coast and the Gulf of Mexico. Besides these sources of production salt is obtained also from mines, as the salt mines in the departments of Huehuetenango and Verapaz, Guatemala.

West Indies.—Salt is produced by solar evaporation of sea water at a number of places in the West Indies. Turks Island, the easternmost of the Bahama Islands, and lying north of Haiti, is the largest producer in the region. Turks Island sea salt reaches the

United Stated in quantities of several thousand tons annually and is used largely for salting fish and meat. The United States ships about 25,000 tons of salt annually to Cuba.

SOUTH AMERICA.

In South America solar salt is produced by the evaporation of sea water in Argentina, Brazil, Venezuela, and other countries, and rock salt is mined in Chile and Colombia. Much of the coarse salt used in South America is imported from Spain, and fine salt from England.

The following notes on salt in South America are quoted from "Mineral deposits of South America," by B. L. Miller and J. T. Singewald, 1919:

Argentina.—The prevailingly arid climate of so much of Argentina and the numerous depressions without outlets result in the presence of many saline lakes, which serve as the sources of the local salt supply. In the southern part of the Province of Buenos Aires is a saline lake the water of which is transported by the South American Salt & Chemical Production Co. (Ltd.) in a 4-inch pipe line to works on the Bay of San Blas, where it is evaporated and yields a salt containing 97 per cent sodium chloride. On the peninsula of Valdez, in Chubut, are two saline lakes which, through the evaporation of the waters in the dry season, contain large quantities of high-grade salt along their margins. A railway has been built to the coast to facilitate shipments. Considerable salt for local use is also produced by solar evaporation of the waters of Lake Bebedero near the city of San Luis.

Brazil.—A large part of the salt consumed in Brazil is imported, although the country is not entirely lacking in salt deposits.

Rock salt is said to have been mined in limited quantities in Matto Grosso and Goyaz. Considerable salt is obtained in the States of Rio Grande do Norte, Alagoas, Sergipe, Ceara, Piauhy, and Rio de Janeiro through the evaporation of ocean water of partially inclosed lagoons.

In the Sao Francisco River valley in Bahia considerable salt is obtained by leaching the surface soils where small ponds have disappeared by evaporation. Naturally such salt contains impurities, as does that obtained from ocean waters.

Chile.—Vast deposits of salt are found widely distributed throughout the arid portion of northern Chile in the salares, which represent desiccated lakes or salt deposits formed by the evaporation of the ascending shallow ground waters. Nevertheless, up to 1902 the country imported a large part of its salt supply. Since then, however, it has entered the export field itself. This is largely the result of the building of an aerial tramway from the Salar Grande, which lies in the southern part of the Province of Tarapaca and about 11 miles inland, to the port of Caleta Pescadores. The Salar Grande covers about 80,000 acres and contains practically pure sodium chloride in enormous quantities. Much of it analyzed 99.99 per cent pure. The thickness of the deposit is not known, but a shaft 82 feet in depth failed to reach the underlying rock stratum.

Although the single deposit at Salar Grande could easily supply the entire country, and the world besides, yet on account of the high cost of transportation many other deposits are worked on a smaller scale to supply the immediate vicinity.

Throughout the western part of the Province of Tarapaca the lowest portions of the salares are covered with thick layers of common salt. These salares present an interesting appearance with their glistening white salt crystals. The surface is not flat, but, instead, everywhere roughened by hummocks or fissured compression ridges up to 3 feet in height. Where railroads cross the salares the track is very rough, owing probably to changes in the surface produced by upheaval as the result of growing crystals obtaining new supplies of material from the ascending ground water.

In a salar near Lagunas, salt is obtained in a unique manner. Ditches are cut in the surface of the salar to a depth of 8 inches below the level of ground water, which here lies at a depth of 3 to 3½ feet. The ditches, exposed to the hot, dry sunshine and parched winds, act as very efficient evaporating pans, and the saline water underlying the salar, exposed in the ditches, is evaporated to the point of saturation when salt begins to crystallize. Since the level of ground water is maintained in the ditches by the constant seeping in of the ground water, the salt continues to accumulate until it reaches the height of ground water, or a thickness of 8 inches, when the ditch has dried up. The salt is shoveled out by hand, and as it is removed the

water again comes in. After a ditch has its salt removed, the same process is gone through again. The rate at which the salt forms is 1 inch in 15 days, or at the rate of three crops of salt a year.

The salt is shoveled out on the ground between the ditches to drain and dry and is then packed in sacks holding 2 quintals each, or about 200 pounds. Most of it is of a beautiful snowy white color and pure enough for table use. Occasionally, however the violent wind storms which sweep across the pampa blow enough of the yellow pampa dust into the ditches to give the salt a dirty color. Such salt is kept separate from the rest and sold for cheaper uses. A branch of the Nitrate Railways to the South Lagunas Nitrate Oficina runs between the salt ditches and affords very convenient shipping facilities.

This salt industry was established on a very small scale about 10 years ago and has proved to be such an inexpensive method that it has grown rapidly, until now there are 150 of these evaporating ditches. Each ditch covers an area ranging about 40 by 40 by 100 feet. The output is about 16,000 quintals a month, which is roughly equivalent to about 10,000 tons annually.

Colombia.—The salt industry is a government monopoly in Colombia, and all salt deposits and saline springs whose waters exceed 6 per cent in saturation are its property. There are three commercial sources of salt, which, arranged in the order of their importance, are:

1. Rock salt found in the Cretaceous or Tertiary beds east of Magdalena River in the Departments of Cundinamarca and Boyaca and the Intendencia del Meta. The most important of these localities is Zipaquira. Others producing salt are Nemocon, Tausa, and Sesquile in Cundinamarca, and Cumaral and Upin in Meta. The deposits are worked either as rock salt or by leaching and evaporation of the concentrated brines. The Zipaquira occurrence consists of a small hill about 2 kilometers in diameter and 250 meters high at the western edge of the town. The salt was worked in an open cut at the summit by the Chibchas before the Spaniards came, but in later years underground mining has been used. González Benito and Davison have calculated the available tonnage at 1,000,000,000. Armenta gives the annual production at 20,000 tons, costing $150,000 and producing for the government a profit of over $350,000. The composition of the salt is stated to be similar to that of sea salt.

2. Salt derived from solar evaporation of sea water along the Caribbean coast. The production from this source is given at 6,000 tons annually.

3. Salt produced from saline springs west of the Magdalena River, where transportation difficulties make the cost of salt from the other two sources excessive. The annual production from this source 10 years ago was about 3,000 tons, but this is decreasing as improved transportation facilities make other salt more readily obtainable because much of it is of inferior quality, containing such salts as sodium sulphate, magnesium sulphate, and sodium bicarbonate in large quantity. The saline springs whose waters are utilized for salt production are located in the Departments of Antioquia, Caldas, Cauca, Narino, and Huila.

Ecuador.—Salt is a government monopoly and is produced in quantity sufficient for domestic use with a small amount for exportation to Colombia.

The greater part of the Ecuadorean salt output comes from the Santa Elena region, where it is produced by solar evaporation. Saline springs yield salt in the Province of Carchi at Mira and Salinas. At Mira the evaporation of saline ground water resulting from saline springs issuing from the underlying trachyte impregnates the sandy soil with salt to a depth of several inches. This sand is collected and the salt washed from it. At Salinas the saline spring waters are evaporated directly for the salt. That obtained from these two localities contains iodine.

Peru.—The salt industry is a government monopoly that maintains a nearly uniform production in the neighborhood of 25,000 tons.

The salt industry is under the control of the Compañía Salinera Nacional, supervised by the government. The production comes from salares along the coast, beds of rock salt, and the evaporation of saline spring water. South of Sechura, in Piura, is a depression into which Piura River overflows in the rainy season. It has leached the saline ground over which it flows, and salt is deposited upon the evaporation of the water in the depression. The Salinas de Morrope in Lambayeque contain a layer of salt from a few to 50 or 60 centimeters in thickness, covered by at least 20 centimeters of sand, over an area 10 kilometers long and 6 kilometers wide. At Guadalupito, Libertad, is a saline marsh of ground water moving toward the sea. Salt accumulates in ditches cut in the marsh through evaporation by sun and wind. Other important producers of similar character to the preceding are the Salinas de Casma, Ancachs, and the Pampas de las Salinas near Playa Chica, Lima. The latter represent desiccated cut-off arms of the sea in which the quantity of salt has been augmented through the aid of ground water resulting from the condensation of fogs. The deposit is 2

miles long, 1 mile wide, and in places several yards thick. It is taken out as rock salt of various degrees of purity according to depth, the purest at the bottom.

At San Blas, Junin, 8 to 10 meters of rock salt are being removed from a bed of unknown thickness. Rock salt is also mined at Cachi, in Huancavelica. At Maras, Cuzco, a stream of salt water, emitted from a mountain, flows down a gulch emptying into the Urubamba River. The water is evaporated in the dry season.

Venezuela.—Salt is one of the important mineral products, and as it is a Government monopoly it has been a source of great revenue to the country.

All of the salt occurs in salt pans in the arid portions, where lakes or arms of the ocean have disappeared by evaporation.

On the peninsula of Araya, opposite Cumana, there is an extensive deposit of practically pure sodium chloride which has been worked ever since the earliest settlement of the country. On the island of Coche, a short distance away, near Barcelona, at Sinamaica, in the northern part of the State of Zulia, and in the State of Falcon, salt deposits of less purity are also worked. Pits dug in the salt pans fill with salt water and on evaporation deposit the salt. The salt obtained from Coche Island is said to be of unusually high quality.

EUROPE.

United Kingdom.—In the United Kingdom the great center of the salt industry is Cheshire, England, where rock salt is mined from very considerable deposits. England not only supplies practically the whole need of the United Kingdom but exports 500,000 tons annually, a large part going to British India. A very small quantity of salt is made in Scotland by evaporating sea water, and in Ireland by evaporationg brine made by dissolving rock salt in sea water. Solar heat is insufficient to make evaporation from sea water alone profitable, so it is strengthened with rock salt and the brine is boiled.

England produces about 2,000,000 tons of salt annually and ships from 15,000 to 40,000 tons of Liverpool salt to the United States.

Central Empires.—Germany is a large producer of salt, the trade in which is largely a syndicate monopoly. The annual production is about 2,000,000 tons. Both rock and brine salt are produced and much of it is from Government-owned mines. The great salt mines at Stassfurt in north-central Germany and at Salzburg, Austria, have long been well known.

Austria and Hungary produce most of their salt from deep mines, which yield about 800,000 tons annually.

France.—Salt is mined in France, and also evaporated from sea water on the Mediterranean shore.

Greece.—Greece makes a considerable output of salt by evaporating sea water.

Italy.—Italy manufactures salt by solar evaporation of sea water, and partly under Government monopoly. Sicily and Sardinia are small producers.

In 1915 the United States imported 11,000 tons of Italian marine salt. This importation was cut off in 1917 and 1918.

Rumania.—In Rumania the domestic supply is obtained by the mining and treatment of rock salt; none by the evaporation of brine.

Switzerland.—In Switzerland salt mines are owned by the several Cantons and most of the domestic supply is obtained from this source.

Russia.—Russia is one of the richest salt-bearing countries of the world. The Donetz Basin is the largest producing area and Orenburg Province is the richest in salt in Russia. Of the domestic production, 500,000 tons, or one-fourth, is rock salt; 1,000,000 tons, or one-half, is from lake bottoms; and the remainder is produced by evaporation of brines from salt wells or deeply buried brines. Five

great salt lakes on the western and southern frontiers of Kooban Province constitute an inexhaustible supply.

Russia's annual production is approximately 2,200,000 tons.

Spain.—Spain produces salt mainly by evaporation of sea water, but a small quantity is derived by mining rock salt. Practically all salt used is of domestic production. There are large deposits of rock salt as yet untouched. The United States imported 34,000 tons of sea salt from Spain in 1916 and 5,000 tons in 1918, most of which was used by fish and meat packers on the Atlantic coast.

Turkey.—Turkey produces and exports salt made by evaporation of ocean brine.

Other countries.—Belgium, Denmark, Norway, and Sweden are not producers of salt. It is stated, however (Commerce Records, October 12, 1918), that experiments in Norway for the extraction of salt from the ocean by electricity have been successful and that two plants will be started in the near future, one in western and one in northern Norway. Each factory is to make 50,000 tons a year. Domestic fisheries will furnish a market.

ASIA.

Aden.—One of the most favorably situated countries in the world for the production of salt by solar evaporation of sea water is Aden, bordering on the Gulf of Aden, south of Arabia. The sea water is said to be more dense than normal, the topography is ideal, and there are few days in the year when the sun does not shine with great heat and intensity. The annual output is about 150,000 tons, practically all of which is exported, principally to Calcutta, India.

China.—China must be a large producer of salt for its millions of inhabitants are dependent on domestic supply. For a great many years salt has been a government monopoly, yielding a large revenue, and importations have been forbidden or restricted. The annual output is estimated at 1,800,000 tons. Salt is produced by solar evaporation of sea water at the coast and of brine from wells and lakes inland, and also by evaporation of brine with artificial heat. There are many producing districts, from Shantung Province on the east to Szechuen Province in western China.

India.—There are four great sources of salt in India—rock salt from the Salt Range and Kohat mines in the Punjab; brine salt from the Sambhar Lake in Rajputana; salt brine condensed on the borders of the lesser Rann of Cutch; and sea-salt factories in Bombay, Madras, and at the mouth of the Indus. In Bengal the damp climate, together with the large volume of fresh water from the Ganges and the Brahmaputra into the Bay of Bengal, render the manufacture of sea salt difficult, and the bulk of the supply, both for Bengal and Burma, is imported from Liverpool, Aden, Egypt, Spain, Italian East Africa, Bombay, and Madras. Nearly every district of Burma is a salt producer. The Tenasserim coast produces 65 per cent and Moulmein more than 52 per cent of the total output. Burma's yield in 1916 was 42,225 tons. The local market is large, because of the extensive native fishing industry. In Southern India the salt industry of Madras Presidency is important and yields 400,000 to 500,000 tons annually. All the salt factories are on the eastern coast of the Presidency.

The production of salt in India amounts to more than 1,000,000 tons annually and in favorable years has been about 1,400,000 tons.

Japan.—Japan produces about 95 per cent of her domestic consumption of salt. Solar evaporation of sea water is the method and source of the supply, and yields about 600,000 tons annually.

Japan imported 1,200 tons of salt from the United States in 1918.

Siam.—Siam, like Japan, derives its supply of salt almost entirely from the solar evaporation of sea water on mud flats along the coast.

AFRICA.

In the countries of northern Africa, most of the salt supply is of domestic origin and is derived from solar evaporation of sea water. In the Union of South Africa, a large part of the salt consumed is taken from shallow lakes or ponds fed by saline springs. There is no salt mining. In most other African countries all the salt that is used is imported.

OCEANIA.

Australia's chief domestic source of salt is in the States of South Australia and Victoria. There is, however, a large importation from England. New Zealand which does not produce salt draws her supply largely from England, but received 11,000 tons from the United States in 1918. It has recently been proposed to produce salt from sea water in New Zealand by the use of hydroelectric power.

In the Philippine Islands salt is now made by solar evaporation of sea water, and, although prior to 1913 much of the salt consumed by the Filipinos was imported from China, the imports are now greatly diminished.

BROMINE.

PRODUCTION.

The bromine marketed in 1918 increased 92.9 per cent in quantity and 96.9 per cent in value over the production in 1917. The marketed output of the last nine years is given in the following table:

Bromine produced and marketed in the United States, 1910–1918.

Year.	Quantity (pounds).	Value.	Average price per pound.
1910	245,437	$31,684	$0.13
1911	651,541	110,902	.17
1912	647,200	145,805	.22
1913	572,400	115,436	.20
1914	576,991	203,094	.35
1915	855,857	856,307	1.00
1916	728,520	951,932	1.31
1917	895,499	492,703	.55
1918	1,727,156	970,099	.56

The prices in the table are derived from the total quantity and value as reported to the Geological Survey by the producers and represent average prices for the year f. o. b. at the plants.

The output in 1918, which was by far the largest in the history of the industry, was made as usual from bittern left after extracting salt from the brine pumped from deep wells at Midland and Saginaw in Michigan; at Pomeroy in Ohio; and at Mason, Hartford, and Malden in West Virginia. Several new wells were drilled near Midland, Mich., in the first half of 1918 to increase the supply of brine.

A large part of the output is not actually marketed as bromine but in the form of potassium and sodium bromide and other salts. The figures given include the bromine content of these salts.

During the first three months of 1918 four of the plants were idle because they were being rebuilt or were short of labor. The effect of this condition on the output and the increase when all plants were running are shown in the following table:

Production of bromine in the United States in 1918.

	Pounds.
First quarter	350,234
Second quarter	492,219
Third quarter	423,526
Fourth quarter	461,177
	1,727,156

Great Britain, France, and Italy were largely dependent on the United States for their supply of bromine in 1918 and large quantities were exported to them for medicinal and other purposes.

Bromine has not been imported into the United States for several years and exports of bromine are not separately reported by the Bureau of Foreign and Domestic Commerce.

PRICE.

The wholesale price of bulk bromine in New York was 25 to 35 cents a pound in 1913 but rose to 50 cents a pound soon after the war began. The increase in price through 1915 to the spring of 1916 and the steady decline since then is shown in the following table, which has been compiled from the Journal of Industrial and Engineering Chemistry. During 1918 the price remained steady at about 75 cents until the armistice was signed and the foreign demand fell off and was 50 cents at the end of the year.

Wholesale price per pound of bulk bromine in New York City, 1915–1918.

	1915	1916	1917	1918
January	$0.40–$0.50	$5.00–$6.50	$1.40–$1.50	$0.75–$0.85
February	.40– .50	5.00– 6.50	1.40– 1.50	.75– .85
March	.40– .50	5.00– 6.50	1.30– 1.40	.75– .85
April	.40– .50	Not quoted.	1.30– 1.40	.75– .85
May	.40– .50	4.75– 5.25	.80– 1.00	.75– .85
June	.85– .87	3.50	.85– 1.00	.75– .85
July	.85– .87	3.50	.55– .60	.75– .85
August	.85– .87	2.40– 2.50	.55– .60	.75–
September	1.00– 1.25	1.30– 1.40	.55– .60	.75–
October	1.25– 1.60	1.20– 1.30	.55– .60	.75–
November	1.50– 1.75	1.40– 1.50	.55– .60	.75–
December	1.50– 1.75	1.40– 1.50	.60– .65	.50–

USES.

Bromine was used extensively in making asphyxiating gases employed in the European war, and after the armistice was signed the demand fell off. Its use in medicine for the treatment of nervous diseases likewise made an increased demand for this material during the war, but this demand still continues. A well-known and continuous use of bromine, both in war and peace, is its application in the form of bromide of silver to photography.

CALCIUM CHLORIDE.

PRODUCTION.

Large quantities of calcium chloride are produced in connection with the ammonia soda process at Solvay, N. Y., Wyandotte, Mich., Barberton and Fairport Harbor, Ohio, Hutchinson, Kans., and Saltville, Va.; but this material derives its calcium from limestone and its chlorine from common salt, and is not an original constituent of the brine pumped at these places. For this reason the calcium chloride so produced is not considered by the Geological Survey in its statistics. Only that calcium chloride which is an original constituent of natural brine and which is produced in connection with the manufacture of salt and bromine from such brine is here recorded. This material is interchangeable for most uses with the waste product of the ammonia soda process, but contains a notable percentage of magnesium. Analyses of calcium chloride obtained from natural brines show from 2 to 6 per cent of magnesium as an impurity. Calcium chloride containing magnesium was made in 1918 at Midland and Saginaw, Mich.; Pomeroy, Ohio; Mason, Hartford, and Malden, W. Va.; and Saltus, San Bernardino County, Calif.

The following table shows a decrease of 12.7 per cent in quantity and an increase of 11.5 per cent in value of calcium-magnesium chloride in 1918:

Calcium-magnesium chloride produced and marketed in the United States, 1910–1918.

Year.	Quantity (short tons).	Value.	Average price per ton.
1910	10,971	$74,713	$6.81
1911	14,606	91,215	6.25
1912	18,550	117,272	6.32
1913	19,611	130,030	6.63
1914	19,403	121,766	6.28
1915	20,535	130,830	6.37
1916	27,709	224,997	8.12
1917	30,503	451,480	14.80
1918	26,624	503,452	18.91

USES.

Calcium chloride is used for the prevention of dust on roads and playgrounds, in brine for refrigerating plants, for protection against fire, for the prevention of freezing, as a drying agent, and for some other purposes. Because of its strong affinity for water, sprinkling with calcium chloride will keep a road moist and therefore dustless

for several weeks. A calcium-chloride solution has some advantage over salt brine in refrigerating machinery for ice factories, meat-packing houses, and cold-storage warehouses. A solution of calcium chloride in fire buckets has an advantage over water in that it does not corrode metal, has a lower freezing point, and because of its affinity for water tends to keep the buckets full by extracting moisture from the air. For this same reason it is used to dry gases, fruits, and vegetables.

FULLER'S EARTH.

By Jefferson Middleton.

GENERAL CONDITIONS.

There was remarkable activity in the fuller's earth industry in 1918. Domestic fuller's earth is used chiefly in refining petroleum, and, as a result of the increase in the production of petroleum, the quantity, value, and average price per ton of fuller's earth sold in 1918 were by far the largest ever recorded by the United States Geological Survey, the increase in quantity being 11,901 short tons, or 16 per cent, and in value $374,267, or 48 per cent, compared with 1917. Although the demand was good, the conditions of labor, fuel, and transportation tended to restrict the output. The imports, on the other hand, on account of the scarcity of bottoms and of the increase in ocean freights, declined 4,387 tons, or 26 per cent. The value of imported fuller's earth (reported as at the foreign port of shipment) decreased $10,882, or 6 per cent. The apparent consumption—production plus imports—increased from 89,561 short tons in 1917 to 97,075 tons in 1918, an increase of 7,514 tons, or 8 per cent. On this basis the domestic production formed 87 per cent of the consumption in 1918, against 81 per cent in 1917. Exports of fuller's earth, if any, were not separately classified.

The most promising development of the year was the utilization of a deposit of earth in Ash Meadows, Nye County, Nev., near Death Valley, Calif., which is reported to be very large. This material is known in the trade as "Death Valley clay," probably because it was first reported as coming from Death Valley, and is said to be excellent for filtering mineral oils.

The mineral advisers of the United States Shipping Board studied closely throughout the war the adequacy of available supplies of fuller's earth to meet war demands. On their recommendation the following regulations were issued by the War Trade Board April 22, 1918:

> No import licenses for shipments made after May 13, 1918, will be granted for fuller's earth except for shipments coming (*a*) overland or by lake from Canada; (*b*) overland from Mexico; (*c*) as return cargo from European countries, and then only when shipped from a convenient port and when loaded without undue delay.

On January 1, 1919, practically all restrictions on the imports of fuller's earth were removed by the following order:

> On and after January 1, 1919, licenses may be issued, when the applications therefor are otherwise in order, for the importation of fuller's earth from any primary or overseas market.

A complete embargo on imports of fuller's earth was not recommended, because it was believed that the domestic output available

for refining edible oils was not sufficient to meet the demand and that it could not be made sufficient in the immediate future. The Shipping Board's inquiries also brought out the interesting information that only domestic fuller's earth is used for the refining of mineral oils. There appears, on the other hand, to be a difference of opinion as to the suitability of the domestic earth for use in refining edible oils. Some of the larger users of fuller's earth, anticipating a shortage of imported material, began early in the war to experiment with domestic earths in refining edible oils and fats, with results so satisfactory that they became independent of imported earth. Others stated that they had experimented with every known domestic earth, but had not found one that completely met the requirements to supplant the imported earth. The requirements of a good earth for refining edible oils are (1) that it shall bleach well and that the oil shall not revert to its original color; (2) that it shall filter well and not cake badly; (3) that it shall leave no permanent disagreeable taste or odor; (4) that the retention of oil in the spent earth shall be small; and (5) that there shall be no spontaneous ignition either in the press or in the waste piles. Those who use the imported earth claim that it is standard in all of these requirements, and that the domestic earth is deficient in one or more of them. Such a defect as inability to bleach well appears to be inherent in some domestic earth, and can not be remedied by treatment. Other defects, such as the taste or odor left by the earth, which is the most frequent objection urged against the domestic material, may possibly be overcome by treatment. Another serious fault charged against the American earth is that it retains a greater proportion of oil than the English earth, which means a direct loss in production; also that it clogs the filter presses more, so that they require more frequent cleaning, which causes further decrease in production. It is also charged that domestic earth is more subject to spontaneous combustion.

OCCURRENCE.

Fuller's earth has been reported in Alabama, Arizona, Arkansas, California, Colorado, Florida, Georgia, Massachusetts, Minnesota, Mississippi, Missouri, Nebraska, Nevada, New York, South Carolina, South Dakota, Texas, Utah, Virginia, and Washington; but it was produced in 1918 only in Alabama, Arkansas, California, Florida, Georgia, Massachusetts, Nevada, and Texas. These eight States, except Alabama and Nevada, were productive in 1917 also. Florida, Georgia, Alabama, Arkansas, and Texas produced 99 per cent of the domestic fuller's earth marketed in 1918.

USES.

Fuller's earth obtains its name from its original use in fulling cloth, but only a small quantity, mainly domestic, is now used in this country for that purpose. It is used principally in bleaching and in clarifying or filtering fats, greases, and oils. It is also used in the manufacture of pigments for printing wall papers, in detecting certain coloring matters in some food products, as a substitute for talcum powder,[1] and, in medicine, as a poultice and as an antidote for alkaloid poisons.

[1] Bur. Mines Bull. 71, p. 19, 1913.

PRODUCTION.

The growth of the industry in the last 10 years and the production in 1917 and 1918 by groups of States are shown in the following tables. The rapid growth of the industry since 1912 is most gratifying. The output in 1918 was more than double and the value more than treble that of 1912. The output in 1918 was 12 times as great and the value 28 times as great as in 1895, the first year of commercial production in the United States. The lowest average price per ton ($5.72) was in 1904; the highest ($13.57) was in 1918; and it was $2.93 higher than in 1917.

Fuller's earth produced and marketed in the United States, 1909–1918.

Year.	Operators reporting sales.	Quantity (short tons).	Value.	Average price per ton.
1909	15	33,486	$301,604	$9.01
1910	17	32,822	293,709	8.95
1911	13	40,697	383,124	9.41
1912	13	32,715	305,522	9.34
1913	10	38,594	369,750	9.58
1914	14	40,981	403,646	9.85
1915	12	47,901	489,219	10.21
1916	10	67,822	706,951	10.42
1917	11	72,567	772,087	10.64
1918	14	84,468	1,146,354	13.57

Fuller's earth produced and marketed in the United States, 1917–18.

State.	1917				1918			
	Number of operators.	Quantity (short tons).	Value.	Average price per ton.	Number of operators.	Quantity (short tons).	Value.	Average price per ton.
Alabama,[a] Florida, Georgia, and Massachusetts	7	67,397	$709,187	$10.52	8	73,395	$1,012,224	$13.79
Arkansas, California, Nevada,[a] and Texas	4	5,170	62,900	12.17	6	11,073	134,130	12.11
	11	72,567	772,087	10.64	14	84,468	1,146,354	13.57

[a] No production from Alabama and Nevada in 1917.

The small number of producers makes it impossible to publish totals for some States without disclosing the output of individual operators; consequently the distribution of output is grouped as above. The Eastern States continue to produce by far the larger part of the fuller's earth marketed; their eight operators reported approximately seven-eighths of the quantity and value of the entire output in 1918. Named in the order of their rank in output the producing States were Florida, Texas, Georgia, California, Arkansas, Alabama, Massachusetts, and Nevada. Florida, which has been the leading State in the production and value of fuller's earth since the beginning of the industry, reported about four-fifths of the total quantity and value in 1918, and Texas rose from third to second place, displacing Georgia.

IMPORTS.

The imports of fuller's earth entered for consumption in 1918 continued to decline, being 4,387 tons, or 26 per cent, less in quantity and $10,882, or 6 per cent, less in value than in 1917. The decrease in quantity was principally in the wrought or manufactured earth (3,846 tons). Both varieties also showed decrease in value. The average price per ton at the port of shipment, as taken from the records of the Bureau of Foreign and Domestic Commerce, for all imported earth increased $2.75; for unwrought earth, $3.54; and for wrought earth, $2.66. The imports in 1918 were the smallest since 1901, except those in 1904 and 1908, but the value of imports in 1918 was exceeded by that of only two years, 1917 and 1914. The imports in 1914 were the largest recorded and exceeded those of 1918 in quantity by 12,370 tons, or 98 per cent, and in value by $29,548, or 18 per cent. With the return of normal conditions the imports in 1919 may be expected to show an increase, though as some of the former larger consumers of imported earth now use domestic earth the increase may not be large. The rates of duty on imported fuller's earth under the act of October 3, 1913, are, on unwrought and unmanufactured earth 75 cents per long ton; on wrought and manufactured earth, $1.50 per long ton.

MAGNESITE.

By Charles G. Yale and Ralph W. Stone.

GENERAL CONDITIONS.

The year 1918 was a trying one for the domestic producers of magnesite. To begin with, temporary restrictions on shipments of freight into the territory east of Chicago because of freight congestion in that district made it difficult to get permission or cars to ship magnesite to the eastern consumers; second, the makers of refractory products practically stopped buying crude magnesite in the fall of 1917 and insisted on having calcined or dead-burned material, because its use would save 50 per cent in weight and in freight charges. Producers that were not equipped with kilns therefore lost business. Furthermore, the prices offered to small producers by some buyers were so low that they had to discontinue operations. At some mines there was a shortage of labor.

By midsummer there was a lack of orders in some fields. Magnesite from Porterville, Calif., was in much less demand for making refractory products, and as building operations were curtailed the call for California magnesite for use in plaster and flooring also diminished. In the fall there was a shortage of labor in both California and Washington, and the restriction on freight shipments to eastern points continued to harass the producers. With the signing of the armistice in November, which was followed by continued activity, but uncertainty in the steel industry, the eastern consumers of magnesite practically stopped placing new orders, probably in the belief that cheaper European magnesite would soon be available.

The imports of calcined magnesite from Quebec, Canada, though small as compared with the output in the United States, may have tended somewhat to reduce the domestic production. In 1917 these imports were about 3,000 tons, but in 1918 they increased rapidly and by May were approximately 2,000 tons a month. The Canadian magnesite contains much lime, but it could be delivered in much less time—a few days instead of several weeks—and at a much lower freight rate than the magnesite from California and Washington.

The condition in California during much of the year was therefore disheartening and a number of small producers and some larger ones suffered considerable financial loss.

The magnesite deposits of the United States as now developed are capable of easily supplying all the domestic demand for many years and of producing a surplus for export. These deposits, however, are in California and Washington, 2,000 to 2,500 miles from the principal market, which is among the steel plants and sanitary flooring plants in the area east of Mississippi River and north of Ohio River.

At the time this is written (June, 1919) the American Mineral Production Co., at Valley, Wash., has been idle for several months; the Northwest Magnesite Co. closed its mine and plant at Chewelah, Wash., in May, 1919; the Sonoma Magnesite Co. and the Refractory Magnesite Co. in Sonoma County, Calif., are idle; the Western Magnesite Development Co.'s mine on Red Mountain, Santa Clara County, Calif., is working at only a fraction of its capacity; and the only companies in California that are mining much magnesite are the White Rock mine, the Porterville Magnesite Co., and the Tulare Mining Co. If Austrian and Grecian magnesite is imported before the stocks of domestic material now on hand are exhausted, it seems likely that the domestic magnesite industry will continue dull.

As one of the largest Austrian deposits is American-owned and as European magnesite may soon be delivered at New York, Philadelphia, and Baltimore at a much lower price than California and Washington magnesite, which has to bear higher wages and very high freight rates, domestic material may not long hold the market in the eastern United States.

MARKETS AND PRICES.

The principal markets for magnesite are the northeastern section of the United States of America and western Europe. This localization is based on the great steel industry, which in turn is centered on the deposits of iron and coal. Magnesite is used as a refractory material in making steel.

The large and long developed deposits of magnesite in Austria-Hungary and Greece supplied the world until recent years, low ocean freight rates making it possible to ship even crude material as far as North America and Australia. A large part of the Austro-Hungarian annual production was used in Germany, England, Russia, France, Belgium, and Italy. Grecian magnesite also was used in large part in western Europe. Formerly the equivalent of 300,000 tons of European crude magnesite was shipped annually to the United States. During 1917 and 1918 almost no foreign magnesite reached America, and the demand made by the steel plants was supplied by California and Washington, whose production of magnesite increased from 11,000 tons in 1914 to 316,000 tons in 1917, and in small part by Canada.

Before the war the price of Austrian crude magnesite per short ton on the Atlantic seaboard was $9 to $10, and Grecian crude was generally valued at a little more than $10. The average price of calcined magnesite at Atlantic ports was about $16.25 a short ton. Dead-burned Austrian magnesite sold as low as $15.72 f. o. b. docks at Philadelphia and $15.60 f. o. b. New York. California crude magnesite was about $8 a ton at the mines, which, with freight to a Pacific port and ocean carriage to Atlantic ports, brought the price of California crude material delivered on the eastern seaboard up to the price of imported calcined material at the same ports. As 1 ton of crude makes only half a ton of calcined magnesite, California material cost twice as much as European material at New York and Philadelphia before the war.

The average value per ton of Washington and California magnesite in 1918 was $7.12 and $9.06, respectively, and as the freight rate to

the Atlantic coast was raised to $15.60, plus 3 per cent war tax, or $16.07, the cost of crude domestic magnesite at Atlantic ports rose to $23 to $25 a ton. New York market quotations in June, 1919, are $30 to $35 a ton for crude magnesite and $50 to $60 for calcined magnesite. There is no European magnesite on the market, but the cost of domestic material is so high that if European magnesite should enter the market, even at double its former price, the magnesite industry of the United States would probably fall back to an annual production of a few thousand tons.

PRODUCTION.

The crude magnesite produced and sold or treated in the United States in 1918 amounted to 231,605 short tons, valued at $1,812,601, f. o. b. mines or plants. As compared with an output in 1917 of 316,838 tons, valued at $2,899,818, this was a decrease of about 27 per cent in quantity and 37 per cent in value. The reduction was not general, however, for while the California output fell from 211,663 tons in 1917 to 84,077 tons, a decrease of 60 per cent, the Washington output increased from 105,175 tons in 1917 to 147,528 tons, or 40 per cent.

According to the best data available, the average price per ton of crude magnesite f. o. b. mine in California fell from $10 in 1917 to about $9.06 in 1918, and in Washington from about $7.45 in 1917 to $7.12 in 1918.

Crude magnesite produced and sold or treated in the United States in 1917–18.

	Quantity (short tons).	Value.		Quantity (short tons).	Value.
1913	9,632	$77,056	1916	154,974	$1,393,693
1914	11,293	124,223	1917	316,838	2,899,818
1915	30,499	274,491	1918	231,605	1,812,601

The quantity of crude magnesite produced and sold or treated in a year is not the same as the quantity mined, for some is mined and not sold, and the stocks on hand vary from year to year. The foregoing table does not include the ore mined but not sold, and therefore these figures do not agree with those reported by the California State Mining Bureau, which represent quantity mined, regardless of whether it was sold. According to the best available information at least 2,300 tons were mined in California but not marketed or treated, and the stock of crude rock in Washington at the close of the year was 8,000 tons.

The Geological Survey has a record showing that about 71,800 tons of California magnesite was calcined before shipment in 1918 and that it made approximately 33,800 tons of calcined and dead-burned magnesite. The remainder of the material sold was calcined after shipment. Thousands of tons of Washington magnesite were shipped crude and a few thousand tons were calcined in the early part of 1918, but during the remainder of the year all the output was made into ferromagnesite at Chewelah, Stevens County, and Irvin, Spokane County. By the fall of 1918 each of the two producing companies in Washington was able to make a monthly output of 4,000 to 5,000 tons of ferromagnesite, or 10,000 tons of crude magnesite.

The large increase in the production of magnesite in the United States began in 1915, and the output from California alone in 1916 had risen from 10,000 tons a year, the normal output, to more than 150,000 tons. This increase before the United States entered the war was due wholly to high prices arising from the stoppage of imports. Government encouragement to the magnesite industry was not necessary, because the raw material is abundant and the prevailing prices insured the mining of a sufficient supply.

During 1918 the Geological Survey received reports of production as of April 1, July 1, and October 1. This quarterly canvass of the industry furnished the data needed by the Council of National Defense, the War Trade Board, the Shipping Board, and other Government bureaus in following closely the progress of this industry. These reports showed that the production of magnesite in the six months ending June 30, 1918, was about 98,500 short tons, of which California produced 53,000 tons and Washington 45,500 tons. The production in the first half of the year was about 43 per cent of the total. Only two companies were producing in Washington in 1918, and one of these stopped quarrying from February to May in order to equip for larger business, thus diminishing the output. Washington made nearly 70 per cent of her production for the year in the second six months, whereas California made 63 per cent of her output in the first six months.

IMPORTS.

The following statistics of imports were obtained from the Bureau of Foreign and Domestic Commerce, Department of Commerce. In this table the imports of 1913 and 1918 are compared to show the decrease in the imports from European countries and the increase in the imports from Canada since the last normal year.

Magnesite calcined, not purified, imported into the United States, in 1913 and 1918.

Country.	1913		1918	
	Quantity (short tons).	Value.	Quantity (short tons).	Value.

1915	99,527,772	255,140	53,148,739	232,071
1916	150,689,445	634,447	18,539,704	204,183
1917	60,554,420	232,105	7,931,159	232,601
1918	10,864,000	103,233	38,098,815	824,022

The following table showing by months the rapid increase and decrease of imports from Canada in 1918 is especially interesting in considering the competition of Canadian with domestic magnesite. The imports from that country had already begun to decline before the armistice was signed.

CONDITION OF INDUSTRY.

CALIFORNIA.

GENERAL FEATURES.

A very marked, discouraging, and unexpected change took place in the conditions affecting the magnesite industry in California in 1918, when, after a period of rapidly increasing prosperity for some five years, the demand for the mineral suddenly ceased. Prices fell to a marked degree; many mines were closed indefinitely and others were compelled to reduce their output from one-third to one-half. Most of the smaller mines and those at a distance from main-line railroads, where hauling by trucks was necessary, had to be closed at once when the demand began to fall off in the earlier months of 1918, and by the middle of the year only the larger mines were operating and even these had materially reduced the rate of output.

Crude magnesite produced in California, 1913-1918.

Year.	Producing mines.	Quantity (short tons).	Value.
1913	1	9,632	$77,056
1914	6	11,293	124,223
1915	16	30,499	274,491
1916	45	154,259	1,388,331
1917	65	211,663	2,116,630
1918	30	84,077	761,811

This table shows that there were 35 fewer producing magnesite mines in 1918 than there were in 1917. The decrease in quantity of ore sold in 1918, as compared with 1917, was 127,586 tons, and the decrease in total value in 1918, as compared with 1917, was $1,354,819. The average price for crude ore f. o. b. railroad shipping point nearest to mine in 1918 was $9.06 a ton and the average price for calcined ore was $36.

In the report on this subject in 1917 an enumeration of the calcining plants in the State is given, together with ownership and exact location. As no changes of note have occurred it is not necessary to repeat this information here.

Two properties in the State, one in Napa County and one in Sonoma County, have natural ferromagnesite ore, which has been found satisfactory to use in refractory products, such as furnace lining and bricks. Magnesite from other California mines has been used for the same products by adding a small quantity of iron. California magnesite, as a rule, is preferred over Washington magnesite for plastic uses because it burns whiter.

REVIEW BY COUNTIES.

Alameda County.—The Cedar Mountain mine, formerly productive, is reported to have plenty of ore in sight but the market price early in the year would not permit of a profit, and later there was no demand, so there was no output. There were several calcining plants in operation in Alameda County but the ore treated was derived from other counties of the State.

Fresno County.—Three deposits in Fresno County were productive in 1918, as compared with nine in 1917. Sinclair Bros. & Ferguson calcined ore from both the Ferguson and the Ward deposits, near Piedra. The plant closed in July, there being no market for the product. The Piedra Magnesite Co., formerly known as the Tarpey mine, operated its rotary kiln only until May 1, and the mine was then closed. The Hughes Creek, Levensaler–Spier, Hazel, Siebert, Terrill, and a few smaller properties were all inactive during the year.

Kern County.—The International Magnesite Co. purchased in January from the Rex Plaster Co., of Los Angeles, the Bissell magnesite deposit in Kern County, but the mine made only a small output in 1918. Early in the year the railroad blockade prevented shipments and later the rise of freight rates caused the mine to close down; it has been virtually abandoned.

Napa County.—In Napa County in 1917 there were seven productive magnesite mines, but in 1918 there were only four. The most prominent producer and, in fact, the largest in the State, was the White Rock (Sweasy) mine, in Pope Valley, where the ore was calcined in upright kilns. This is one of the two mines in the State which produces a natural ferromagnesite that is utilized for refractory purposes. Other producers were the White Cape, at Chiles Valley, the White Horse and Giant, and the Soda Creek. The two latter mines closed down as only part of the output was sold. The Tulare Mining Co., in Chiles Valley, reported a small output in the first quarter of 1918. Two of the kilns of Sears & Cubbage were used by the owners of the White Rock mine, in 1918. The Minerals Development Co., at Rutherford, went out of business in 1918 and made no production.

Riverside County.—The Magnesco Refractory Products Co. worked the old Winchester property in Riverside County part of the year. The ore from this mine is hand picked on a belt conveyor before going to the rotary calciner.

San Benito County.—A small output was made by the San Benito Magnesite Co. near New Idria in San Benito County and also from the Sampson deposit in the early part of the year. Before summer all mining ceased and the kilns were idle.

Santa Clara County.—Several claims near Madrone, in Santa Clara County, owned by the Bay Cities Water Co., were operated productively by lessees but were finally closed in the latter part of 1918 through lack of demand for the product. The Western Magnesite Development Co. on Red Mountain made a large output in the early months of the year, but the demand fell off entirely after July 1. This property was operated under a receivership. The Chicago and some adjoining unnamed claims were worked by the John D. Hoff Asbestos Co. for about six months, when lack of demand caused cessation of operations. The Standard was worked by lessees and reverted to the owner, Mrs. S. L. Stock, in July. A small quantity of ore was produced by J. H. Plattner from the Wasp mine on Red Mountain but not sold. All other properties on the Santa Clara County side of Red Mountain were unproductive in 1918.

Sonoma County.—The Sonoma Magnesite Co., near Cazadero, operated the most productive mine in Sonoma County in 1918. The entire output was calcined in the rotary kilns at the mine. A small

output was made by the Leighton mine near Cloverdale. The Harker magnesite mine at Guerneville utilized its product in the manufacture of light carbonate of magnesia and has established this manufacture on a commercial basis. The Refractory Magnesite Co., near Preston, ground finely all its calcined material which is a natural ferromagnesite and made it into magnesite brick. The brick is manufactured at Stockton, San Joaquin County, and meets with ready sale at satisfactory prices. No output was made by any of the following known magnesite mines of the county: Standard Group, Cazadero; Cloverdale and Melville Ranch, at Cloverdale; Guerneville Farm Co., on Gillam Creek; Lucky Elsie and Sotoyome, at Healdsburg; and Morey deposit, at Warfield.

Stanislaus County.—The Bald Eagle mine, at Ingomar, Stanislaus County, owned by the Gustine Magnesite Co., made some output, but the ore was sold in the crude state to be calcined elsewhere. The Middletown mine, at Ingomar, shipped its ore for calcination to the Sedan Calcined Magnesite Co., at Emeryville, Alameda County, which controls the property. The most productive mine in the county was that of the Red Mountain Magnesite Co., formerly known as the Butcher. Shipping ceased at the mine at the end of June. The Manzanita, Burr Bros.' mine, and a few smaller mines were not operated during the year.

Tulare County.—For many years Tulare has been the leading county in California in the production of magnesite, but in 1918 her output was exceeded by that of Napa County. This was due to the activities of one large property in Napa County and to the curtailment of shipments from two of the larger mines in Tulare County because a certain extensive manufacturing enterprise, formerly drawing its supplies of calcined material from Tulare County, obtained them in 1918 from the State of Washington, as being nearer the point of consumption. The most productive mines in the county were those of the Tulare Mining Co., and the Porterville Magnesite Co., both near Porterville and both equipped with calcining plants. The ore from the mine of the Hawley Paper & Pulp Co. and the Lindsay Magnesite Co. is mixed and sold with the product of the Tulare Mining Co., which operates both properties. The ore of the Dinuba Magnesite Co. is sold crude. The customers of this property, as of some other mines, ceased buying ore and began to obtain their supplies from the State of Washington. The Rocky Hill (Duryea) mine, at Exeter, sold its ore crude. The Schrei mine, at Lindsay, made only a nominal output, there being little demand. The Oakland Magnesite Co., of Porterville, sold only crude ore, and there was no market for that after May. Among the idle mines in Tulare County, owing to lack of demand for the product, were the Blue Crystal and Montgomery, at Lindsay; and the American Magnesite Co., Avery, Hathway, Howeth, and Magnesite Refractories Co., at Porterville.

WASHINGTON.

Only two companies operated in Washington in 1918. The smaller of these mined more than twice as much magnesite as the largest producing country in California. Bad roads that made delivery to the railroad difficult in 1917 were overcome by a railroad direct to the quarries of one company and a 5-mile aerial tram to the quarry of the other.

The American Mineral Production Co., shipping magnesite from Valley, Wash., changed its method of mining from quarrying to driving tunnels and taking the rock out through large funnel-like pits discharging into a tunnel beneath. The rock was calcined in vertical shaft kilns until March, after which it was shipped to Irwin, Wash., and there dead-burned in rotary kilns of the Inland Portland Cement Co. The American Mineral Production Co. did not produce magnesite after the signing of the armistice, when orders ceased because of the unsettled condition of the steel industry and the well-stocked magnesite market. According to H. F. Wierum, general manager of the company, production in 1918 was retarded by incomplete development up to the time of quitting (Dec. 1), by car shortage in the early months of the year, by labor shortage and influenza, and by the fact that the company was learning the business of sorting and calcining magnesite. At the end of 1918 the business was practically at a standstill, although some old contracts held over and were being filled early in 1919.

The Northwest Magnesite Co., shipping from Chewelah, made calcined magnesite in January and February, 1918, then stopped producing during March, April, and May to remodel its plant, so that a large output of ferromagnesite could be made. The manufacture of ferromagnesite began June 1 and continued to the end of the year. During the summer unusually dry weather caused a shortage of hydroelectric power and retarded production for a time. An auxiliary power plant of two gas engines having a combined capacity of about 400 horse power was installed to remedy this condition. R. B. Rogers, superintendent, reports that "unavoidable lack of development and preparation to meet the demand" retarded production by the Northwest Magnesite Co. in 1918.

The Valley Magnesite Co. made no production in 1918. Three shaft kilns with steel jackets were built and an aerial tram was delivered to the mine, which is on Deer Creek about 13 miles from Valley and close to the Red Marble quarry of the American Mineral Production Co. The latter company built a railroad from Valley to its Allen and Moss mines, 5 miles out, and built the grade, trestles, and bridges to Deer Creek, 8 miles farther. The output from the Allen and Moss mines proved sufficient, and although ties were cut and placed along the right of way the ties and rails were not laid on the last 8 miles of grade. Until this is done the Valley Magnesite Co. can ship only by making a long haul over a bad wagon road at a cost of $4 or more a ton.

The Crosby Magnesite Co. holds magnesite claims about 13 miles west of Valley on Deer Creek, near the Double Eagle mine of the Valley Magnesite Co. Development on these claims consisted in blasting and clearing away a small portion of rock at the base of the deposit, preparatory to opening up the face of a quarry. No magnesite was shipped during 1918.

NEW MEXICO.

According to Mr. J. H. Cauthen, general manager of the Great Eagle mine, Lordsburg, N. Mex., there is a body of magnesite from 1,000 to 1,500 feet long and at least 30 feet wide in the vicinity of the mine. The sample submitted by him in August, 1918, is to all

appearances identical with the general run of magnesite occurring in veins and lenses in serpentine at many places in California. Mr. Cauthen furnished the following analysis made by Regis Chauvenet & Bro., St. Louis, Mo.:

Analysis of magnesite from Lordsburg, N. Mex.

Silica	0.60
Oxides of iron	.38
Calcium carbonate	4.03
Magnesium carbonate	94.99
	100.00

This analysis is lower in silica and higher in lime than most analyses of California magnesite in the tables on pages 151–152.

USES.

Practically all the magnesite produced in Washington is made into synthetic (artificially combined) ferromagnesite and goes in the dead-burned form to steel plants and to manufacturers of refractory products east of the Mississippi. None, so far as known, is used for plastic purposes, probably because it is not pure white. For Sorel cement white material is preferred so that white plaster may be used or may be colored by the addition of mineral pigments to suit the consumer's taste.

During the last three years a very large part of the California magnesite has been used for refractory purposes, and it is worthy of note that the entire output of the White Rock mine in Napa County, the largest producer in the State in 1918, is used by Pacific coast steel plants in their basic open-hearth and electric furnaces. The Refractory Magnesite Co.'s mine at Preston likewise yielded a natural ferromagnesite which was made into refractory brick at Stockton and used by smelters in California and Utah. The natural ferromagnesite of these two mines has made California a reputation for magnesite suitable for refractory as well as for plastic purposes. Whether the amorphous magnesite of California and the crystalline magnesite of Washington are equally suitable for refractory uses, in spite of claims for each, is a question which has arisen, but, so far as the Survey knows, has not been answered with incontrovertible evidence. From the little evidence in hand it would seem that technically they may be of equal value and that choice between them is based on results of calcination, difference in cost delivered to consumer, and time required for receipt of shipments.

All California magnesite, however, is not of the same composition. The two deposits mentioned above contain enough iron to constitute the product a natural ferromagnesite. The other productive deposits, so far as has been learned, carry only a very small percentage of iron.

ANALYSES.

The Geological Survey has not systematically sampled the magnesite mines in California and Washington, but the following analyses made in the chemical laboratory of the Survey from samples collected by Government geologists show the character of some of the material in a number of different deposits. The following table contains analyses of samples collected by R. W. Stone in 1917:

Analyses of crude and calcined magnesite from California and Washington.

[Chase Palmer, analyst.]

There is the possibility that some of the analyses given in these tables may not fairly represent the product of a mine because the rock from different parts of a mine may vary somewhat in composition. For instance, the analysis of a sample taken from the bunker of the White Rock mine, Pope Valley, Napa County, Calif. (No. 1) is claimed by Frank R. Sweasy, who operates the mine, to be too low in iron and too high in lime.

Of all the California magnesite here shown, that of the White Rock mine, Napa County, Calif., is highest in iron content and at the same time reasonably low in silica and lime. Material from two small properties (Nos. 17 and 18) in Santa Clara County carries as much iron, but one is high in silica and the other is high in lime. The

Refractory Magnesite Co.'s ore (No. 31) also is unusually high in iron. Many analyses of Washington magnesite made by reputable chemists have shown 1 to 3 per cent of calcium oxide, 1 to 2 per cent of iron oxide, and silica commonly between 2 and 6 per cent. It should not be concluded from the analyses herewith that the magnesite from the Finch quarry (23) is commonly so low in silica or that from the Allen quarry (25) commonly so high as shown.

FOREIGN DEPOSITS.

CANADA.

Quebec.—The principal magnesite deposits in Canada are in the Grenville district, Argenteuil County, Quebec. The deposits so far discovered in the Grenville district are in four principal localities about 12 miles north of Grenville. In general it may be said that the magnesite in all its occurrences is found in association with the metamorphosed group of sediments—crystalline limestone, garnet gneiss, and quartzite.

The magnesite in the Grenville district is a glistening cream-white to milk-white or gray crystalline material occurring in extensive masses associated with bands or lenses of dark-green to light-yellow serpentine. Throughout the great mass of the deposits magnesite and dolomite are so similar in appearance that the presence of dolomite is difficult to detect.

The most conspicuous structural features of the magnesite deposits are their prevailing lenticular forms. The deposits have been intensely faulted, crumpled, and otherwise deformed.

Outcrops of the deposits are as much as 1,000 feet in length and 300 feet in width. It is estimated that there are in sight 686,900 tons of magnesite containing less than 12 per cent CaO, and 483,700 tons of magnesite-dolomite containing more than 12 per cent CaO. These deposits were quarried extensively in 1918.

British Columbia.—In the Atlin mining district both magnesite and hydromagnesite have been observed, but extensive masses of hydromagnesite near the town of Atlin are the most important. These deposits are superficial beds of fine powdery white hydromagnesite 6 to 8 feet thick and covering areas 18 acres in extent. Two groups of these deposits are estimated to contain 180,000 tons of hydromagnesite. Shipments were made in 1918. The presence of magnesite is recorded also at Illecillewaet in the Kootenay district, on Germansen Creek in the Omineca district, at 108 Mile House on the Caribou road in the Lillooet district, and near the northwest end of Liza Lake in Bridge River district. Magnesite occurs also in other localities in Canada.

MEXICO.

On the island of Santa Margarita, in Magdalena Bay, Lower California, there are extensive deposits of magnesite from which exports have been made to the United States. Magnesite of the California type crops out on the hillsides, and hundreds of thousands of tons are said to be in sight. Large quantities can be obtained without mining and need only to be broken up for shipment. This ore was calcined in 1917 in a plant at Chula Vista, San Diego County, Calif.

VENEZUELA.

Deposits of magnesite of the California type occur on Margarita Island off the coast of Venezuela. Most of them are in the northern part of the island, and the most accessible are along the beach. The supply of magnesite is estimated at 3,200,000 tons in six groups of deposits. An average of many analyses shows that the magnesite contains less than 0.5 per cent each of lime, iron, alumina, and silica. It is reported that the Magnesite Products Corporation, of New York, acquired 7,000 acres in 1916 estimated to contain 300,000 tons of magnesite. In 1915, 500 tons of magnesite were shipped to the United States, but there have been various hindrances to making shipments from the island in more recent years.

AUSTRIA-HUNGARY.

The magnesite deposits of Austria-Hungary, which until recently furnished much of the world's supply, follow a northeast line that extends for several hundred miles across the two countries. The mineral occurs in lenses, some of which are very large, and 10 or more of them are commercially workable. All the lenses are isolated, and many of them are too small to be worked profitably. The Austrian deposits extend across the Province of Steiermark, with the west end near the city of Salzburg and the east end near the town of Gloggnitz. The Veitsch deposit has been worked longer than the others. It is a huge lens on an isolated hill surrounded by barren rocks. The distance from the top to the base of the magnesite on the hill face is 700 to 800 feet. The mineral is quarried in a series of benches about 50 feet apart vertically.

Another very large deposit in Austria is at Radentheim, on the north side of the Millstatter Alps. The magnesite is quarried by great cuts, lowered by gravity to rotary kilns, and shipped from Trieste.

The Hungarian deposits extend from Totpelsoc to Kassa and eastward, perhaps into Russia. The largest deposits in Hungary are between the towns of Jolsva and Nyustya. The largest operations are at Nyustya, Gomor County, where the beds worked range from 150 to 300 feet in width and the rock is quarried by benches 50 feet high.

The magnesite contains chemically combined iron and is crystalline, two properties which cause it to calcine readily to the dead-burned state and make very satisfactory grain magnesite and brick for refractory purposes.

GERMANY.

Small irregular veins of magnesite in serpentine were worked for many years at Baumgarten and Grochan, south of Frankenstein, Silesia, but it is not known whether they are productive at present.

SPAIN.

In the Province of Santander in northern Spain, about 60 kilometers by rail from the seaport of Santander, coarse crystalline magnesite occurring in Lower Cretaceous limestone and dolomite has been

mined for a number of years. The productive area is near Reinesa, between Fresno and Mina. Production has ranged from 500 to 2,000 tons in a year.

GREECE.

Grecian magnesite is of the noncrystalline type and occurs associated with serpentine in veins, masses, and stockworks. The largest veins are 50 feet or more in width and several hundred feet long. The best deposits are on the island of Euboca. The Eubocan deposits are all close to the seashore, and under normal conditions cheap water transportation to the principal magnesite markets of the world is available. In 1912 the output was equivalent to about 150,000 tons of crude magnesite, exclusive of the product of one of the three largest producers.

The magnesite from Greece is practically identical in physical and chemical character with that from California.

Skiathas Island contains magnesite, probably in serpentine; there is no record of production.

MACEDONIA.

Magnesite is found in large quantities in Macedonia near the coast not far from the Greek border. It is of the compact type and occurs as veins in serpentine. The principal field covering several square miles lies 5 to 10 miles south of Salonika.

ITALY.

Magnesite veins of workable thickness occur at Castiglioncello and at Monternfoli, near the seaport Livorno, and have been worked in recent years. There are veins up to 10 inches thick in the Turin district, and on the island of Elba there is a stockwork of small veins in serpentine which has yielded several thousand tons.

NORWAY.

Magnesite occurs in Norway at Snarum, in the Modums division of Buskerud bailiwick, 35 miles from Dammen, the nearest city and seaport. It occurs as small veins in serpentine, but, unlike other magnesite in serpentine, it is crystalline.

SWEDEN.

Deposits similar to those in Norway are found in Sweden near Narbotten in Kvickjock parish on the north side of Terra River, and in Paturkorso Valley between Sulitelima and the North Sea. Veins $1\frac{1}{2}$ and $4\frac{1}{2}$ meters thick have been found.

RUSSIA.

Magnesite has been mined in the Orenburg government, east of Ufa, but no information is at hand regarding the character, extent, or ownership of the deposits. One mine yielded 26,320 metric tons in 1906. Other deposits are reported about 300 verts farther south, far from railroad. Magnesite occurs also in the Kuban district, on the north slope of the Caucasus Mountains.

TRANSVAAL.

Extensive deposits of magnesite occur between Kaapmuiden and Malelane (Barberton district?), 2 miles south of the Pretoria-Delagoa Bay Railway, 87 miles from Lourenco Marquez. The magnesite is found in a great number of veins, 4 feet in maximum thickness, and has been mined to a depth of 100 feet. Most of the veins are much less than 3 feet wide, but there seems to be a large area of serpentine carrying them. Irregular veins of magnesite as much as 3½ feet wide occur also near Jacktlust, 51 miles southeast of Pietersburg.

RHODESIA.

Magnesia is reported to occur in Mashonaland, notably at Umtali and, in steatite, at the great Zimbabwe ruins. Probably it is in the form of magnesite.

PORTUGUESE WEST AFRICA.

Great deposits of magnesia are reported in the volcanic district of North Bihe, 200 miles east of Benguela. The deposits are near or associated with boiling springs and may be hydromagnesite.

INDIA.

Madras.—The most important occurrence of magnesite in India seems to be in the Chalk Hills, 4 miles northwest of Salem, Madras Presidency, in the southern part of the India peninsula. The magnesite occurs in interlacing veins, some of which stand several feet above the surrounding talcose, serpentinized, and other magnesian rocks. The main magnesite deposits occur over an area of 10 square miles and they have yielded more than 2,000 tons in a single year.

Mysore.—Magnesite deposits occur at a number of points near Mavinhalli and Kadakola, in Mysore, in the south-central part of the India peninsula. They do not seem to be of commercial importance, though the magnesite has been used locally as a substitute for lime. Deposits of unknown extent are reported near Yelwai.

ASIA MINOR.

Magnesite is reported in beds 3 to 15 feet thick, near Eskechehio station in Saruchan province, Turkey in Asia, about 75 kilometers from Smyrna.

MANCHURIA.

Coarsely crystalline magnesite that occurs as a bed in dolomite and limestone is exposed for long distances along the railroad in Manchuria Mountains. It is mined at Daisetsukyo, north of Darien.

AUSTRALIA.

Queensland.—All the deposits of magnesite in Queensland are so small that they probably have no commercial value. The deposit at Kilkivan is thought to be the largest.

New South Wales.—In New South Wales rounded blocks of pure-white magnesite outcropping over an area of 100 acres 3½ miles

northwest of Fifield constitute the largest deposit reported. Many thousand tons is available at small cost, and 16,000 tons has been marketed. Veins and stockworks in serpentine at Attunga have yielded 2,000 tons, and veins 2 to 10 feet wide at Piedmont, near Barraba, have yielded 500 tons.

South Australia.—Large deposits of magnesite are reported in South Australia. One in Flinders Range, 11 miles east of Port Pirie, was worked to provide refractory material for smelters. Other deposits are 5 miles from Tumby Bay and at Robertstown.

Western Australia.—In Western Australia short irregular veins 2 feet thick occur at Bulong, northeast Coolgardie; and in Victoria veins 1 to 6 feet thick are known at Heathcote and a vein 2 to 4 feet wide occurs near Redesdale.

TASMANIA.

Magnesite deposits are reported in Tasmania but they may be merely mineralogic and not commercial occurrences.

NEW CALEDONIA.

Extensive deposits of magnesite occur on the north end of the west coast of New Caledonia. A small quantity has been exported.

WORLD'S PRODUCTION.

World's production of magnesite (estimated) in 1913 and 1917, in metric tons.

Country.	1913	1917
Australia	220	8,500
Austria-Hungary	[a] 400,000	(b)
Canada	1,600	[c] 58,000
Greece	96,600	145,000
India	16,000	17,640
Italy	600	.....
Spain	900	1,500
Transvaal	600	780
Turkey	8,000	(b)
United States	8,740	287,400
Mexico, Norway, Russia	5,000	5,000
	538,260	523,820

[a] Exports. [b] No data available. [c] Production in 1918.

The totals in the table above are of no value except as showing that the world's production of magnesite exceeds 500,000 tons annually. Austria-Hungary exported 400,000 tons in 1913 and may have used an equal quantity. If so the world's output would have been nearer 1,000,000 tons. Presumably the production of these countries for domestic use did not decrease during the war and may have equaled that of the rest of the world. No data are available on which to base an estimate.

PRODUCERS OF MAGNESITE IN 1918.

CALIFORNIA.

1. California Magnesia Co., Guerneville.
2. Dinuba Magnesite Co., E. H. Kemble, secretary, Merchants National Bank Building, San Francisco.
3. Edward Duryee, Hollingsworth Building, Los Angeles.
4. Geo. W. Elder, 799 Oak Street, San Francisco.
5. Hugo Fischl, Hollister.
6. Dr. Carl G. Gohlin, St. Helena.
7. Gustine Magnesite Co., Ingomar.
8. H. L. Haehl, Humboldt Bank Building, San Francisco.
9. John D. Hoff Asbestos Co., Monadnock Building, San Francisco.
10. Fred Leighton, Cloverdale.
11. Magnesco Refractory Products Co., Winchester.
12. Nichelini & McKenzie, Chiles.
13. Oakland Magnesite Co., Realty Syndicate Building, Oakland.
14. Piedra Magnesite Co., 1411 Merchants National Bank Building, San Francisco.
15. J. H. Plattner, Patterson.
16. Porterville Magnesite Co. of California, Porterville.
17. Red Mountain Magnesite Co., Russ Building, San Francisco.
18. Refractory Magnesite Co., Preston.
19. Dr. R. Schiffman, Pasadena.
20. E. F. Schrei, Lindsay.
21. Sedan Calcined Magnesite Co., 253 Russ Building, San Francisco.
22. Hugh Sherlock, Madrone.
23. Sinclair & Ferguson, Fresno.
24. Sonoma Magnesite Co., Humboldt Bank Building, San Francisco.
25. Standard Magnesite Co., Livermore.
26. J. W. Swan, San Bernardino.
27. Frank R. Sweasy, Humboldt Bank Building, San Francisco.
28. Tulare Magnesite Co., 310 Sansome Street, San Francisco.
29. Western Magnesite Development Co., 704 Clunie Building, San Francisco.

WASHINGTON.

1. American Mineral Production Co., 732 Marquette Building, Chicago, Ill.
2. Northwest Magnesite Co., Chewelah, Wash.

SODIUM AND SODIUM COMPOUNDS.

By Roger C. Wells.[1]

INTRODUCTION.

The various compounds of sodium consumed in the United States, with the exception of common salt, are obtained chiefly by chemical processes, but small quantities of so-called natural soda and sodium sulphate are made each year from natural deposits of these salts. The natural salts are also usually subjected to some refining process before use, so that practically every sodium compound, except common rock salt, may be considered a manufactured product. It is obvious, however, that no report which does not include the total production of all the compounds can adequately represent the industry.

The continued cooperation of the principal producers of sodium compounds in supplying data on production as well as other information of general interest to the trade is hereby gratefully acknowledged.

DISTRIBUTION OF SODIUM IN NATURE.

The element sodium is very widely distributed in nature. It forms about 2.36 per cent of known terrestrial matter and is the most abundant of the alkali metals. Sodium appears to occur in nature only in combination with other elements, if its alleged occurrence as the free element in blue rock salt is neglected.

Sodium is an important constituent of the feldspars and several other insoluble minerals from which sodium salts are not extracted commercially, but which are nevertheless regarded as the ultimate source of the salts that are soluble in water.

Sodium chloride is obtained by simple evaporation from sea water, the water of the Great Salt Lake, and many natural brines. Sodium carbonate and trona are thus obtained from the water of Owens Lake. The brine of Searles Lake yields on complete evaporation sodium chloride, sodium sulphate, sodium carbonate, and sodium borate, but these salts can be separated only by elaborate treatment.

The soluble salts above mentioned, as well as sodium nitrate, are found at or near the surface in dry desert regions, but elsewhere they are carried in solution to the sea. The deposits of sodium nitrate in northern Chile and the deposit of sodium carbonate at Magadi, British East Africa, are conspicuous examples of accumulation due to favorable geologic and climatic conditions. Many beds of rock salt in various regions have probably originated similarly and have been preserved from solution by impervious covers. Large deposits of salt

[1] The statistics of production in this report were collected by Miss A. T. Coons, of the United States Geological Survey.

have been found at considerable depths in Michigan, Kansas, Louisiana, Texas, and New York, in the Stassfurt region in Germany, at Salzburg in Austria, in the Province of Orenberg in southeastern Russia, at Northwich in Cheshire, England, in Alsace and Lorraine, and in many other regions. From the soluble natural or crude salts are derived all the refined salts described in the following pages.

TRADE NAMES FOR VARIOUS SODIUM COMPOUNDS.

The name soda was originally used to mean sodium oxide, Na_2O, the name being analogous to those of other basic oxides. However, it has long been used in trade for the carbonate and in household economy for the bicarbonate and the hydrated carbonate, known as sal soda, and is frequently applied indiscriminately to all compounds of sodium, as "nitrate of soda." The better usage is to call such substances "sodium" compounds—for instance "sodium nitrate"—to prevent ambiguity.

The following table gives the various trade names, the chemical formula of the important constituent, the usual percentage of the compound designated in the marketed product, and the ordinary chemical name:

Trade names and formulas of sodium compounds.

Trade name.	Formula.	Percentage.	Chemical name.
Soda ash	Na_2CO_3	98–100 Na_2CO_3	Sodium carbonate.
Sodium sesquicarbonate, trona.	$Na_2CO_3.NaHCO_3.2H_2O$	47 Na_2CO_3, 37 $NaHCO_3$	Hydrated sodium carbonate-sodium bicarbonate.
Sal soda, washing soda, crystal carbonate.	$Na_2CO_3.10H_2O$	37.1 Na_2CO_3	Hydrated sodium carbonate.
Bicarbonate of soda, baking soda, saleratus.	$NaHCO_3$	99.5–99.7 $NaHCO_3$	Sodium bicarbonate or acid sodium carbonate.
Caustic soda	NaOH	75–99 NaOH	Sodium hydroxide.
Soda lime	NaOH+CaO		Sodium hydroxide and calcium oxide.
Borax	$Na_2B_4O_7.10H_2O$	52.7 $Na_2B_4O_7$	Sodium tetraborate.
Tincal			
Sodium hyposulphate	$Na_2S_2O_3.5H_2O$	64 $Na_2S_2O_3$	Sodium thiosulphate.
"Hypo."			
Yellow prussiate of soda	$Na_4Fe(CN)_6.10H_2O$	62.7 $Na_4Fe(CN)_6$	Sodium ferrocyanide.
Red prussiate of soda	$Na_3Fe(CN)_6.H_2O$	94 $Na_3Fe(CN)_6$	Sodium ferricyanide.
Sodium nitroprusside	$Na_2Fe(CN)_5NO.2H_2O$	88 $Na_2Fe(CN)_5NO$	Sodium nitroprusside.
Salt cake	Na_2SO_4	98–100 Na_2SO_4	Sodium sulphate.
Niter cake	$NaHSO_4$	61–86 $NaHSO_4$	Sodium bisulphate or sodium acid sulphate.
Glauber's salt	$Na_2SO_4.10H_2O$	44.1 Na_2SO_4	Hydrated sodium sulphate.
Chile saltpeter	$NaNO_3$	95–96 $NaNO_3$	Sodium nitrate.
Soda niter			
Water glass	$Na_2O.4SiO_2$ (approx.)		Sodium silicate.
Sodium carbonate monohydrate.	$Na_2CO_3.H_2O$	85–86 Na_2CO_3	Sodium carbonate monohydrate.

SUMMARY OF PRODUCTION.

The rule of the United States Geological Survey that the production of any single mineral or compound shall not be disclosed unless there are at least three producers of it or special permission is obtained, has necessitated reporting the production of some compounds in the following table in groups. The table summarizes the reported production of sodium and sodium compounds in 1918 and gives for comparison such figures as are available for 1917.

Sodium and sodium compounds produced in the United States in 1917 and 1918.

	1917		1918	
	Quantity (short tons).	Value.	Quantity (short tons).	Value.
Sodium (metal)	(a)	(a)	264	$153,437
Sodium acetate	1,049	$225,828	2,622	460,783
Sodium benzoate			203	886,058
Sodium bicarbonate	119,177	4,029,499	118,535	3,293,153
Sodium bichromate and sodium chromate	22,446	9,045,133	28,334	9,868,118
Sodium bisulphite and sodium sulphite	13,707	300,668	16,362	478,482
Sodium bromide			574	438,730
Sodium carbonate:				
Soda ash	1,390,625	38,028,000	1,390,628	35,635,520
Monohydrate and sesquicarbonate	55,035	1,262,875	22,678	482,958
Sal soda	77,939	1,698,520	82,465	2,020,271
Sodium chlorate and sodium perborate	2,915	1,333,426	2,413	1,004,250
Sodium chloride: [b]

[a] Included in miscellaneous compounds.
[b] Stone, R. W., Salt, bromine, and calcium chloride; U. S. Geol. Survey Mineral Resources, 1918, pt. 2, pp. 119–121, 1919.

The production given in this table is practically identical with sales for most of the salts. This is especially true of soda ash, as the soda ash used by manufacturers in making caustic soda in their own plants is not included in the figures above. On the other hand, however, the caustic soda made and consumed in their own plants by paper manufacturers and others is included, as well as small quantities of certain other salts listed below, such as sodium bichromate, salt cake, and niter cake, consumed by the makers. A large quantity of niter cake is neither sold nor consumed but represents a waste product.

Sodium compounds used by the makers in their own plants in 1918.

	Quantity (short tons).	Value.
Soda ash	664,119	$13,627,000
Sodium acetate	2,236	349,085
Sodium bichromate	3,227	812,310
Sodium fluosilicate	87	12,975
Sodium hydroxide	79,207	5,077,891
Sodium silicate	56,696	1,076,621
Sodium sulphate:		
Glauber's salt	7,001	138,820
Niter cake	39,906	259,672
Salt cake	9,903	207,080
Sodium sulphide	3,269	153,967

Sodium salts derived from natural sources in 1917 and 1918.

	1917		1918	
	Quantity (short tons).	Value.	Quantity (short tons).	Value.
Sodium chloride:				
Salt in brine	2,890,588	$1,083,586	2,830,600	$1,245,265

Evaporated salt	2,482,564	14,959,261	2,724,203	20,010,435
Sodium carbonate, sodium bicarbonate, and sodium sulphate	21,743	895,602	24,053	992,788
	6,999,920	20,836,044	7,262,797	27,933,149

IMPORTS.

Sodium nitrate is the principal sodium salt imported. The imports of most of the other salts are very small compared to the domestic production, according to the records of the Bureau of Foreign and Domestic Commerce, which furnishes the data on imports and exports.

Sodium salts imported for domestic consumption in 1917 and 1918.

	1917		1918	
	Quantity (pounds).	Value.	Quantity (pounds).	Value.
Sodium arsenate	23,296	$2,404	35	$88
Sodium benzoate	42,561	197,284	54,150	11,469
Sodium bicarbonate[a]	35,737	1,660	12,383	629
Sodium carbonate:				
Soda ash	2,063,571	70,080	1,445	29
Monohydrate and sesquicarbonate	45,650	1,179	44,800	1,281
Sal soda	100	5	25	2
Sodium chlorate	33,600	1,080	44,810	8,066
Sodium chloride (common salt)	129,844,300	280,135	80,580,700	281,468
Sodium chromate and sodium bichromate	22,025	4,075	5,102	1,184
Sodium cyanide	1,622,118	826,052	69,279	12,615
Sodium ferrocyanide (yellow prussiate of sodium)	22,048	13,454	271,063	98,505

Sodium thiosulphate, or sodium hyposulphite	5,840	5,748	1,120	975
	3,601,665,180	62,527,007	4,223,449,559	90,939,431

[a] Or supercarbonate, or saleratus, and other salts containing 50 per cent or more of sodium bicarbonate.

EXPORTS.

The domestic exports of sodium salts in 1918 were only slightly less than those in 1917, which were the largest ever recorded.

Value of domestic sodium salts exported, 1914–1918.

1914 (July 1 to Dec. 31)	$1,320,963
1915	7,725,034
1916	17,571,439
1917	23,384,969
1918	22,291,735

Domestic sodium salts exported in 1917 and 1918, by classes.

a Compiled from records of Bureau of Foreign and Domestic Commerce.

SODIUM COMPOUNDS IN RELATION TO THE WAR.

The war not only stimulated the chemical industry in the United States to produce sodium compounds that were formerly imported and to supply them to foreign countries, but, on account of the high cost of potash, brought about the replacement, either wholly or in part, of potassium compounds by sodium compounds in the manufacture of glass, soap, and matches, in photography, in medicine, in tanning, and in the manufacture of cyanide for extracting the precious metals from their ores. The need of chlorine for war purposes led to an increased production of caustic soda, which was itself in demand for making phenol used in making the picrates.

From August 1 to November, 1918, the exportation of caustic soda was under Government control through license. About the time the armistice was signed the prices of nearly all sodium compounds, which were then greatly advanced over pre-war prices, began to fall, and the decline continued well into 1919, leaving the producers in a very uncertain position with regard to possible tariff changes, foreign competition, and domestic demand.

Operation of the Government plant at Edgewood, Md., for making caustic soda and chlorine was discontinued in November, 1918. Most of the caustic soda made in this plant was used in the form of a dilute solution for absorbing residual obnoxious gases incidental to the production of the "war gases."

Although the present prices of many sodium compounds do not compare favorably with those of corresponding potassium compounds before the war, it is practically certain that pre-war prices for potassium compounds will not be again reached for a long time, so that the greater part of the substitutions that have occurred will be permanent. It may be noted that if the costs of production of sodium salts are equal to those of the corresponding salts of potassium per "molecule" the sodium salts have a slight advantage in lightness and hence in freight rates, as the atomic weights are 23 and 39, respectively.

The demonstrated inventiveness of the chemists and producers of the United States indicates that foreign competitors will not easily regain their former position in this country. Moreover, with one or two exceptions, raw materials are abundant in the United States, so that foreign competition will always have the handicap of the long ocean haul, although this may be cheaper than a long land haul. Obviously, however, a certain amount of international exchange is desirable, and it may be noted that although both imports and exports have increased in recent years the increase in imports has been due largely to sodium nitrate, whereas that in exports has been due to a considerable variety of manufactured compounds.

The principal producers of alkali in the United States have organized an export association under the laws of the State of Delaware, with offices at 171 Madison Avenue, New York City. The object of the association is to work for uniform and favorable conditions in the export business, with special regard to foreign banking facilities and to ocean freight rates.

SODIUM (METAL).

The production of metallic sodium in the United States in 1918 amounted to 264 short tons, valued at $153,437. These figures can not be compared with similar figures for 1917, as reports were received from only two producers in that year, but the production in 1917 is included under the heading of miscellaneous compounds.

Metallic sodium is used in the manufacture of sodium cyanide, sodamide, sodium peroxide, and indigo, as well as in the laboratory. It has been proposed to use it in desulphurizing petroleum, and some was formerly used in reducing such metals as magnesium and titanium from their chlorides.

Metallic sodium is made commercially by electrolyzing fused sodium hydroxide at about 330° C. The Darling process, formerly used at Philadelphia, employed sodium nitrate. Attempts have been made to use the chloride, but its high melting point (800° C.) introduces many difficulties.

Sodium may also be made by heating sodium carbonate or other sodium salts with charcoal, and when so made it is separated from the reaction mixture by distillation. Patents have been granted for producing metallic alloys by electrolysis, the alloys being run off and the sodium distilled.

In United States patent 1265360, issued to W. L. Morrison, May 7, 1918, it is proposed to make a basic sodium silicate and hydrogen from caustic soda and silicon or ferrosilicon, and then to make metallic sodium from the sodium silicate by means of more silicon and lime.

The production of alkaline metals from fused halides by electrolysis forms the subject of United States patent 1258529, issued to J. Brode, March 5, 1918.

Metallic sodium was produced in 1918 by—

Dow Chemical Co., Midland, Mich.
Niagara Electro Chemical Co., 100 William Street, New York, N. Y.
Semet-Solvay Co., Syracuse, N. Y.

SODIUM ACETATE.

Sodium acetate, crystals of which have the formula $NaC_2H_3O_2.3H_2O$, is manufactured in the process of purifying acetic acid obtained in the distillation of wood. It is used in making acetic acid and dry colors, in dyeing, in photography, in purifying glucose, and in medicine. Sales of this material in the United States in 1918 amounted to 2,622 short tons, valued at $460,783, compared with 1,049 short tons, valued at $225,828, in 1917.

Sodium acetate was manufactured in 1918 by

Anderson Chemical Co., Wallington, N. J.
Dow Chemical Co., Midland, Mich.
Grasselli Chemical Co., Cleveland, Ohio.
Heyden Chemical Works, 135 William Street, New York, N. Y.
Maas & Waldstein Co., 92 William Street, New York, N. Y.
McKesson & Robbins (Inc.), 91 Fulton Street, New York, N. Y.
Mallinckrodt Chemical Works, St. Louis, Mo.
Powers-Weightman-Rosengarten Co., Philadelphia, Pa.
E. R. Squibb & Sons, 78 Beekman Street, New York, N. Y.

SODIUM BENZOATE.

Sodium benzoate ($NaC_7H_5O_2$) is manufactured from benzoic acid, which is obtained from light tar oils by several processes, from gum benzoin, or is made synthetically. Its principal use is as a preservative. A small quantity is also used in medicine, in making certain aniline blues, and in printing textiles.

The production reported to the United States Geological Survey for 1918 amounted to 203 short tons, valued at $886,058.

Sodium benzoate was manufactured in 1918 by

Chromos Chemical Co., Aeolian Hall, New York, N. Y.
Doherr, Grimm & Co., 87 Gold Street, New York, N. Y.
Heyden Chemical Works, 135 William Street, New York, N. Y.
Hord Color Products Co., 1636 Columbus Avenue, Sandusky, Ohio.
Mallinckrodt Chemical Works, St. Louis, Mo.
Niagara Alkali Co., Niagara Falls, N. Y.
Seydel Manufacturing Co., 86 Forrest Street, Jersey City, N. J.
E. R. Squibb & Sons, 78 Beekman Street, New York, N. Y.
C. H. Stuart & Co., Newark, N. J.

SODIUM BICARBONATE.

Sodium bicarbonate, or mono sodium carbonate, familiarly known as baking soda ($NaHCO_3$), if theoretically pure has the composition Na_2O, 36.90 per cent; H_2O, 10.72 per cent; CO_2, 52.38 per cent. It is commercially known in grades specifying the percentage purity of the salt itself, the greater part reported being 99.5 to 99.7 per cent. Its principal use is in baking.

The domestic production reported in 1918 was 118,535 short tons, valued at $3,293,153, compared with 119,177 short tons, valued at $4,029,499, in 1917. These figures do not include material that is mixed with soda ash and used in cleaning compounds.

In the following table the production of sodium bicarbonate for the years 1899, 1904, 1909, and 1914 is taken from the report of the Bureau of the Census,[1] and for the other years the figures are supplied by the Geological Survey.

Sodium bicarbonate produced in the United States in certain years.

	Quantity (short tons).	Value.		Quantity (short tons).	Value.
1899	68,856	$1,332,765	1916	115,117	$2,303,540
1904	68,869	1,135,610	1917	119,177	4,029,499
1909	82,800	1,515,045	1918	118,535	3,293,153
1914	90,169	1,439,014			

Sodium bicarbonate is the first product obtained in the manufacture of sodium carbonate by the ammonia process, as described on page 173. The bicarbonate made in this way, however, contains a small quantity of ammonia, which renders it unfit for most purposes for which sodium bicarbonate is used, and it must be treated further to obtain a pure salt—for example, it may be either partly calcined and recarbonated or entirely recrystallized or reprecipitated under suitable conditions.[2]

[1] Chemicals and allied industries: Census of manufactures, p. 18, U. S. Dept. Commerce Bur. Census, 1918.
[2] Martin, Geoffrey, The salt and alkali industry, p. 79, London, 1916.

The following firms manufactured sodium bicarbonate in 1918:

Mathieson Alkali Works (Inc.), Saltville, Va.
Michigan Alkali Co., Wyandotte, Mich.
Natural Soda Products Co., Keeler, Calif.
Solvay Process Co., Syracuse, N. Y.

SODIUM BICHROMATE AND SODIUM CHROMATE.

Sodium bichromate ($Na_2Cr_2O_7.2H_2O$) has come into extensive use in the last few years in tanning leather on account of the scarcity of the potassium bichromate previously used, and is said to be just as satisfactory as a tanning agent. It is also used in making paints, in refining the precious metals obtained from the cyanide solution by means of zinc, as a mordant, principally in wool dyeing, and as a laboratory reagent.

In making sodium bichromate sodium chromate is first made by heating the mineral chromite with soda ash and lime. The object of the lime is to prevent fusion and keep the mass porous to facilitate oxidation. The roasted mass is extracted with water containing some sodium carbonate to convert any calcium chromate into sodium chromate, and after separation of the solids the solution is allowed to crystallize or is treated with sulphuric acid to form sodium bichromate, which is freed from the sodium sulphate by evaporation and crystallization.

Sodium chromate ($Na_2CrO_4.10H_2O$) is not used so extensively as the bichromate, on account of its hygroscopic character and because of its lower content of chromic anhydride.

The production of these two salts in the United States in 1918 amounted to 28,334 short tons, valued at $9,868,118, as compared with 22,446 short tons, valued at $9,045,133, in 1917.

The imports of sodium bichromate and sodium chromate in 1918 were 5,102 pounds, valued at $1,184, as compared with 22,025 pounds, valued at $4,075, in 1917.

Sodium bichromate is manufactured by the following firms:

Martin Dennis Co., Newark, N. J.
E. I. du Pont de Nemours & Co., Wilmington, Del.
Grasselli Chemical Co., Cleveland, Ohio.
Mutual Chemical Co. of America, 55 John Street, New York, N. Y.
National Electrolytic Co., Niagara Falls, N. Y.
Natural Products Refining Co., Jersey City, N. J.
Sawyer Tanning Co., Napa, Calif.
Sherwin Williams Co., Cleveland, Ohio.

Sodium chromate is also made by the Mutual Chemical Co. of America and the Mallinckrodt Chemical Co.

SODIUM BISULPHITE AND SODIUM SULPHITE.

Sodium sulphite (Na_2SO_3), sodium bisulphite ($NaHSO_3$), and sodium polysulphite are all made from sodium carbonate and sulphur dioxide and are used as a source of sulphur dioxide in making wood pulp, sterilizing brewer's casks, as reducing agents in photography, dyeing, and bleaching, as a depilatory in cleaning hides, and for removing traces of chlorine where a chlorine bleach has been used. Sodium sulphite may also be made by heating a mixture of sodium sulphate and iron in an atmosphere of sulphur dioxide.

The total production of these salts in the United States in 1918 amounted to 16,362 short tons, valued at $478,482, compared with 13,707 short tons, valued at $300,668 in 1917.

The following list gives the domestic manufacturers of sodium sulphite, sodium bisulphite, and sodium polysulphite, in 1918:

Sodium sulphite:
Charles Cooper & Co., 194 Worth Street, New York, N. Y.
Grasselli Chemical Co., Cleveland, Ohio.
Mechling Bros. Manufacturing Co., Camden, N. J.
Semet-Solvay Co., Syracuse, N. Y.
Sodium bisulphite:
Atlantic Carbonic Co., 268 Third Street, Chelsea, Mass.
Charles Cooper & Co., 194 Worth Street, New York, N. Y.
Grasselli Chemical Co., Cleveland, Ohio.
A. Lee Co., Lawrence, Mass.
Charles Lennig & Co., 112 South Front Street, Philadelphia, Pa.
Mallinckrodt Chemical Works, St. Louis, Mo.
Mechling Bros. Manufacturing Co., Camden, N. J.
Merrimac Chemical Co., 148 State Street, Boston, Mass.
D. D. Williamson & Co., 86 Fulton Street, New York, N. Y.
Sodium polysulphite:
Charles Cooper & Co., 194 Worth Street, New York, N. Y.

SODIUM CARBONATE.

SODA ASH.

PRODUCTION.

Soda ash is the commercial term used for normal sodium carbonate without water of crystallization (Na_2CO_3; theoretically Na_2O 58.49 per cent, CO_2 41.51 per cent). It is supplied commercially in various grades, described, according to reports of the Department of Commerce,[1] as 58 per cent, dense 58 per cent, 48 per cent, special 48 per cent, and 36 per cent. The percentages refer to the content of sodium (expressed as Na_2O). The figures reported by the producers in 1918 were all for the 58 per cent grade.

The soda ash produced and marketed as such in the United States in the calendar year 1918 amounted to 1,390,628 short tons, valued at $35,635,520. This compares with 1,390,625 short tons, valued at $38,028,000 in 1917, and with 1,194,183 short tons, valued at $16,464,774 in 1916. These figures do not include sodium carbonate reported in the form of monohydrate and sesquicarbonate nor the soda ash consumed by the manufacturers in their own plants in making caustic soda and other sodium compounds. The quantity of soda ash used for the latter purpose in 1918 was about 664,000 short tons, against 482,000 short tons in 1917. The following table gives such figures as are available for the annual production of soda ash:

Soda ash produced in the United States in certain years.[a]

	Quantity (short tons).	Value.		Quantity (short tons).	Value.
1899	390,653	$4,859,656	1916	1,194,183	$16,464,774
1904	518,954	8,204,545	1917	1,390,625	38,028,000
1909	646,057	10,362,656	1918	1,390,628	35,635,520
1914	935,305	10,937,945			

[a] The figures for 1899, 1904, 1909, and 1914 are from Chemicals and allied industries: Census of manufactures, p. 18, U. S. Dept. Commerce, Bur. Census 1918.

[1] Chemicals and allied industries: Census of manufactures, p. 23, U. S. Dept. Commerce Bur. Census, 1918.

This table shows a fairly normal increase until the beginning of the war. Since that time the increase has been rapid. It was estimated by Weldon [1] in 1883 that the entire soda trade of the world (sodium carbonate and sodium hydroxide in terms of sodium carbonate) amounted annually to only about 709,000 tons, a figure that shows, when compared with the present production in the United States alone, how rapidly chemical industry has advanced.

The manufacture of soda ash in the United States is confined almost entirely to New York, Ohio, Virginia, Michigan, California, and Kansas.

The following is a list of the producers of soda ash in 1918:

Columbia Chemical Co., Pittsburgh, Pa.
Diamond Alkali Co., Pitsburgh, Pa.
Mathieson Alkali Works (Inc.), Saltville, Va.
Michigan Alkali Co., Wyandotte, Mich.
Solvay Process Co., Syracuse, N. Y.
West Virginia Pulp & Paper Co., New York, N. Y.
California Alkali Co., San Francisco, Calif.
Inyo Development Co., Keeler, Calif.
Natural Soda Products Co., Keeler, Calif.

Of these nine companies the first five manufacture their material from salt brine, the last three have deposits of the natural salt, and one company incinerates the ash from spent pulp liquor.

IMPORTS AND EXPORTS.

The imports of soda ash for consumption in the United States in 1918 were less than 1 ton, according to the records of the Bureau of Foreign and Domestic Commerce, Department of Commerce. In 1917 they amounted to 1,032 short tons, valued at $70,080.

The exports in 1918 amounted to 119,217 short tons, valued at $7,805,550. For the last six months of 1917, the only period for which figures are available for 1917, the exports amounted to 49,210 short tons, valued at $2,884,569. The principal countries receiving this material in 1918, named in decreasing order of quantity exported to each, were Japan, Canada, Brazil, Australia, and Cuba. Japan received 47,442 short tons, valued at $3,417,074, and Canada 36,613 short tons, valued at $1,911,488.

PRICES.

The price of soda ash in the United States was hardly affected by the European war until late in 1915 and early in 1916. Quotations then rose to several times the previous figures, but during the summer and fall of 1916 the price fell somewhat, and remained fairly steady until the summer of 1917. In September, 1917, the Government was bidding insistently for caustic soda and the price of soda ash advanced to its highest point—light soda ash in bags was quoted at $4.20 a hundred pounds in the New York market. The price soon fell to about $3, however, and remained there for nearly the whole of the first quarter of 1918. It then fell to nearly $2, subsequently rose again to $2.60, and when the armistice was signed began a

[1] Sodium: Encyclopedia Britannica, 9th ed.

decline that continued well into 1919, stopping at about $1.50. The average price in 1918 was therefore considerably lower than that in 1917.

It should be remembered that spot quotations usually fluctuate more widely than prices made on long-term contracts by large manufacturers, and also that prices regularly quoted in the New York market are much higher than those representing the value of the marketed product in large lots f. o. b. at point of shipment.

USES.

Sodium carbonate in the form of soda ash is the foundation of the alkali industry, for it is used in the manufacture of glass, soap, and dyes, as well as of caustic soda and most other sodium compounds. It is second only to lime and limestone in cheapness and general applicability as a base. It is used directly in making glass and after conversion into sodium hydroxide or other sodium compounds it is used in nearly all the chemical industries, especially in making soap, wood pulp, paper, dyes, explosives, bleach liquor, and cleansing preparations and in tanning.

MANUFACTURE.

GENERAL STATEMENT.

Sodium carbonate is present in the ashes of certain seaweeds and was long obtained from this source along the shores of France, Spain, and Great Britain. The origin of the name "soda ash" is doubtless thus explained. About 13 tons of ash is said to produce 1 ton of sodium carbonate and 30 pounds of iodine as a by-product. About 1775 the want of sodium carbonate was so greatly felt that the French Academy in that year offered a prize for the discovery of a profitable method of making it from common salt. This prize was won by Leblanc in 1791 for the process known by his name, which involves the preparation of sodium sulphate and its conversion into sodium carbonate. The Leblanc process was of great value to the chemical industries from the first quarter of the nineteenth century until recent years. It has been forced to give way gradually to the Solvay or ammonia process and to electrolytic methods. At present the ammonia process holds the field and increasing attention is being paid to natural soda, the utilization of which is determined very largely by costs of transportation. The Magadi deposit of natural soda in British East Africa has been estimated to contain 200,000,000 tons of soda, and enormous quantities of soda are known in certain areas in the western United States.

CONVERSION OF SODIUM SULPHATE INTO SODIUM CARBONATE.

Sodium sulphate, prepared either by heating salt with sulphuric acid or obtained in some other way, is heated with coal and limestone to form "black ash," the chemical changes being indicated by the following equation:

$$\underset{\text{sodium sulphate}}{2Na_2SO_4} + \underset{\text{calcium carbonate}}{3CaCO_3} + \underset{\text{carbon}}{9C} = \underset{\text{sodium carbonate}}{2Na_2CO_3} + \underset{\text{calcium oxide}}{CaO} + \underset{\text{calcium sulphide}}{2CaS} + \underset{\text{carbon monoxide}}{10CO}$$

Upon lixiviation of the black ash the calcium compounds remain mostly insoluble and sodium carbonate goes into solution together with various impurities. The solution usually carries considerable sodium hydroxide and may be worked for either sodium hydroxide or sodium carbonate.

If sodium carbonate is to be prepared, the solution (specific gravity 1.28) is carbonated, filtered, and evaporated, yielding, if evaporated at boiling heat, crystals having the formula Na_2CO_3. The crystals are removed from the solution and heated to dry them completely. The product, "soda ash," carries 98 to 99 per cent sodium carbonate, 0.8 per cent sodium sulphate, 0.1 per cent sodium chloride, 0.1 per cent sodium sulphite or sodium thiosulphate, a little insoluble matter, and about 0.7 per cent moisture.

The "alkali waste" left after the lixiviation of the black ash for sodium carbonate and sodium hydroxide, which contains unchanged coal, calcium carbonate, and calcium sulphide, is now worked for sulphur by the Chance-Claus process. This process is summarized by the equation

CaS	+	CO_2	+	H_2O	=	$CaCO_3$	+	H_2S
calcium sulphide		carbon dioxide		water		calcium carbonate		hydrogen sulphide

The calcium carbonate thus produced can be recovered and used again, and the sulphur is recovered either as sulphur or ultimately as sulphuric acid.

In England, where the Leblanc process is still used to some extent, it is generally customary to convert the black ash liquor directly into sodium hydroxide instead of sodium carbonate. This is done as described under "Sodium hydroxide," page 185.

AMMONIA PROCESS.

The manufacture of sodium carbonate by the ammonia or Solvay process occupies to-day a very prominent position in the chemical industry and probably has only natural soda to fear in competition, although the electrolytic production of caustic soda is a factor to be reckoned with.

The reactions on which the process depends were known as early as 1852, but the mechanical details of treatment were first perfected by Ernest and Alfred Solvay in the late sixties and have been constantly improved. The process rests on the slight solubility of sodium bicarbonate in ordinary salt brine containing ammonium bicarbonate. The brine is saturated with ammonia and subjected to the action of carbon dioxide when, in consequence of the formation of the bicarbonate ion in solution, sodium bicarbonate is precipitated. The latter salt is removed by filtration and the mother liquor containing ammonium chloride is treated to recover ammonia. The sodium bicarbonate is calcined to produce soda ash and carbon dioxide which is again used in the process. The final product is "light" soda ash which for certain purposes is converted into "heavy" ash, comparable with Leblanc soda ash, which is preferred by the glass-making industry. The ammonia soda ash is of exceptional purity, running 99 to 99.7 per cent of sodium carbonate (Na_2CO_3).

Plants for the manufacture of soda ash by the ammonia process must be situated near good supplies of salt and limestone in order to avoid excessive charges for transportation.

The principal waste product of the ammonia process is calcium chloride. Some of this is sold for use in manufacturing and as a dust-laying compound. Lime mud is sold for use as a fertilizer.

CRYOLITE PROCESS.

Sodium carbonate may be made from cryolite by heating it with limestone, extracting with water the sodium aluminate thus formed and decomposing the solution thus obtained with carbon dioxide. The sodium carbonate is finally separated in solution from the insoluble aluminum hydroxide precipitated by the treatment with carbon dioxide, and dehydrated to form soda ash. Soda ash made in this way is said to be very pure.

RECOVERY OF SODA ASH FROM SPENT PULP LIQUOR.

A number of pulp and paper mills that use the soda process of making fiber for the manufacture of paper recover sodium carbonate almost continuously from the spent liquor by evaporating the solutions and incinerating the residues, thus saving a quantity estimated at 80 to 90 per cent of the soda ash required. So far as known limestone and sodium sulphate are not added to increase the yield of soda ash in this procedure, though the Leblanc process would suggest the possibility.

ELECTROLYTIC PROCESS.

It is reported that the Hargreaves-Bird process of making sodium carbonate from salt by electrolysis is used in some of the plants of the West Virginia Pulp & Paper Co. and the New York-Pennsylvania Co., both companies at 200 Fifth Avenue, New York City. This process consists in carbonating the cathode solution in which caustic soda would otherwise be formed. The carbon dioxide is obtained from limekilns in which the lime used in causticizing the sodium carbonate is made. It is claimed that this process produces a carbonate solution that contains very little sodium chloride and can be causticized directly, whereas the usual electrolytic caustic solution must be freed from sodium chloride, also that the diaphragms last a long time, so that the process results in ultimate economy of operation.

The sodium carbonate reported as made by paper mills from spent liquor and by electrolysis in 1918 amounted to 39,277 short tons.

MONOHYDRATE AND SESQUICARBONATE.

When a solution of sodium carbonate evaporates above 35.1° C. the resulting crystals have the formula $Na_2CO_3.H_2O$. This salt is termed monohydrate or crystal sodium carbonate. It dissolves in water with the evolution of heat.

The sesquicarbonate ($Na_2CO_3NaHCO_3.2H_2O$), which when found in nature is known as trona, is prepared by allowing a solution containing proper proportions of sodium carbonate and sodium bicar-

bonate to crystallize at a temperature above 35° C. It is said to possess the advantage of being neither efflorescent nor deliquescent.

The production of these two salts reported to the United States Geological Survey in 1918 was 22,678 short tons, valued at $482,958, compared with 55,035 short tons, valued at $1,262,875 in 1917.

SAL SODA.

Sal soda, hydrated sodium carbonate, washing soda, or crystal carbonate, having the chemical formula $Na_2CO_3.10H_2O$, is made from soda ash by dissolving it in water and allowing the solution to crystallize below 32° C.

The production of sal soda in the United States in 1918 was 82,465 short tons, valued at $2,020,271. The output for the years for which figures are available is shown in the following table:

Sal soda produced in the United States in certain years.[a]

	Quantity (short tons).	Value.		Quantity (short tons).	Value.
1899	63,249	$875,243	1914	106,591	$1,510,449
1904	59,548	831,869	1917	77,939	1,698,520
1909	86,644	1,156,882	1918	82,465	2,020,271

[a] The figures for 1899, 1904, 1909, and 1914 are taken from Chemicals and allied industries: Census of manufactures, p. 18, U. S. Dept. Commerce Bur. Census, 1918.

Sal soda is used in softening water and for many other purposes for which soda ash is used where purity is an essential requirement. It is also used in cleansing compounds or alone as washing soda.

The imports for consumption of sal soda into the United States, according to the records of the Department of Commerce, were practically negligible in both 1917 and 1918. The exports in 1918 amounted to 6,358 short tons, valued at $213,865.

During the last six months of 1917 there was exported 3,718 short tons of sal soda, valued at $97,772, of which more than half went to Canada and more than 25 per cent to Argentina.

The following firms reported the production of sal soda in 1918:

California Soap Co., 2437 Ninth Street east, Los Angeles, Calif.
Central Chemical Co., foot of Chapel Street, Newark, N. J.
Church & Dwight Co., 22 Cliff Street, New York, N. Y.
Citrus Soap Co., Ninth and K Streets, San Diego, Calif.
Columbia Chemical Co., Pittsburgh, Pa.
Columbus Crystal Co., 15 Arch Street, Newark, N. J.
Detroit Soda Products Co., 2595 Jefferson Street west, Detroit, Mich.
Fresno Soap Co., Fresno, Calif.
E. Griswold & Co., Sixth and Parker Streets, West Berkeley, Calif.
Humes Manufacturing Co., 110 Water Street, East Providence, R. I.
Iowa Soda Products Co., Detroit, Mich.
Los Angeles Soap Co., 633 First Street east, Los Angeles, Calif.
Mechling Bros. Manufacturing Co., Camden, N. J.
Morton Salt Co., 80 Jackson Boulevard east, Chicago, Ill.
Mount Hood Soap Co., 110 Fourth Street north, Portland, Oreg.
O'Neil Oil & Paint Co., Milwaukee, Wis.
Pennsylvania Salt Manufacturing Co., Philadelphia, Pa.
C. T. Perry & Co., Helena, Mont.
Phenix Supply Co., Atlanta, Ga.
John Reardon & Sons Co., Allston Street, Cambridge "A," Mass.

Stauffer Chemical Co., 624 California Street, San Francisco, Calif.
Valley Chemical Manufacturing Co., 11 North Market Street, Chicago, Ill.
Vera Chemical Co., Hopkins and Villard Avenues, North Milwaukee, Wis.
Warnock & Ralston, 429 Second Street, Rock Island, Ill.
Western Alkali Refining Co., Omaha, Nebr.
John C. Wiarda & Co., Brooklyn, N. Y.

NATURAL SODA.

ANALYSES.

In the arid regions of western Nevada and southeastern California the soluble salts which accumulate by evaporation of surface waters in undrained basins in consequence of the deficient rainfall consist largely of sodium carbonate and sodium bicarbonate, together with sodium chloride and sodium sulphate. The largest accumulations are found in "playas" or "playa lakes," which are usually dry in summer but are covered with a few inches of water in winter. Many analyses of the incrustations deposited from playa lakes have been made. For examples the reader is referred to Clarke's "Data of geochemistry."[1] According to F. T. Shutt and E. A. Smith (Canadian Chemical Jour, vol. 2, p. 196, 1918) the data obtained in the study of the nature and concentration of alkali in semiarid districts of western Canada have aided in the classification of the areas into irrigable and nonirrigable lands.

The analyses of alkaline lake waters and incrustations given below are typical.

Analyses of alkaline lake waters.

	1	2	3	4	5	6	7

UTILIZATION OF NATURAL SODA IN WESTERN STATES.

LOCALITIES OF COMMERCIAL PRODUCTION.

The United States Geological Survey long ago called attention to the value of the natural soda in the Western States.[1] The deposits have been worked commercially in a number of places, at first for local consumption and later for wider use as transportation facilities became available. Natural soda has been suggested as cheap and effective in all processes where purity is not a prime requisite, as in treating ores by flotation. Moreover, the extraction of potassium salts, principally potassium chloride and potassium sulphate, from natural brines and lake waters, has recently been carried out conjointly with the production of sodium salts, especially sodium chloride, sodium bicarbonate, and sodium tetraborate, and the methods of separating these various salts are being studied and improved constantly.

The firm of Huff, Tebbe & Weed, of Dunsmuir, Calif., shipped some crude natural soda to San Francisco in 1917, where it was refined and placed on the market by the Soda Refining Co., of San Francisco.

Natural soda has been produced commercially at the following places:

"Union Pacific Lakes,"[2] 13 miles south of Laramie, Wyo.
"Downey" lakes, 18 miles southwest of Laramie, Wyo.
Soda lakes, Ragtown, Nev.
Long Valley, southeast of Mono Lake, Calif.
Owens Lake, Inyo County, Calif.
Grant County, Wash.
Green River, Wyo.
Vernon, Calif.
Dorris, Calif.
Antioch, Nebr.
North of Clinton, British Columbia.[3]

Chatard [1] pointed out the favorable conditions that exist at Owens Lake for the production of sodium carbonate and studied the process of fractional crystallization of the dissolved material. From his results it appears that the first crop of crystals consists largely of trona ($Na_2CO_3NaHCO_3.2H_2O$). The companies now producing soda at Owens Lake, however, report soda ash as their principal product.

The original operator at Owens Lake was the Inyo Development Co. The plant of this company north of Keeler, with about 3,000 acres of land, has now been turned over to the California Alkali Co., which constructed a new plant at Cartago in 1917. The latter company worked over some low-grade sodium carbonate in 1918 that had formed from seepage from the evaporating vats of the Inyo Development Co.

The usual process at Owens Lake consists in evaporation of the lake water in open vats until a deposit of trona is formed. The trona is then heated to form soda ash. Another process consists in evaporating the water and then introducing carbon dioxide to precipitate sodium bicarbonate.

The Natural Soda Products Co., of Keeler, Calif., reported the production of both sodium carbonate and sodium bicarbonate in 1918, the latter, however, as crude material carrying 76 per cent $NaHCO_3$.

A new plant is being constructed by the Soda Products Corporation of California, 308 Call Building, San Francisco, for making soda from the water of Owens Lake. This plant had not been completed, nor had any soda been produced up to May, 1919.

The Western Alkali Refining Co., 820 World Herald Building, Omaha, Nebr., reported the production in 1918 of sodium carbonate in the form of sal soda at its plant at East Omaha, Nebr. This salt was obtained in purifying crude potash salts produced at Antioch and Hoffland, Nebr., and therefore represents natural soda. The crude potash salts are said to run about 60 per cent sodium carbonate.

A new use for natural soda has recently been proposed in the manufacture of so-called mineral soap, which is made from flocculated clay, oil, and sal soda.

FOREIGN DEPOSITS OF NATURAL SODA.

Lake Magadi.—The Magadi Soda Co. (Ltd.), Kajrado, British East Africa, has been formed to develop the deposit of natural soda covering about 6 square miles, known as Lake Magadi, and the material is to be refined in England. The deposit is said to contain at least 200,000,000 tons of soda.

Pretoria.—At what is called the Salt Pan in the Pretoria district, South Africa, natural soda is found in a deep crater-like depression and extends to a considerable depth. The material consists partly of trona and partly of mud impregnated with salt and soda, from which the soda has to be extracted and recrystallized. Soda also occurs in this district as an efflorescence resulting from the evaporation of solutions derived in the weathering of granite.[2] The reported production of soda in the Union of South Africa in 1918 was valued at about $47,000.[3]

PATENTS FOR TREATING ALKALI BRINES.

That the separation and utilization of the several salts occurring in the deposits of natural soda in the Western States offer interesting problems in chemical engineering is shown by the patents issued in recent years.

United States patent 1254521, issued January 22, 1918, to J. R. MacMillan, describes the separation of sodium and potassium carbonates. The solution is evaporated to a specific gravity of 1.39, treated with carbon dioxide to separate sodium bicarbonate, and then cooled to 0° to cause deposition of potassium bicarbonate. After evaporating the mother liquor the process is repeated.

SODIUM CHLORATE.

Sodium chlorate ($NaClO_3$) is prepared from sodium carbonate and chlorine or from sodium hydroxide and chlorine or by the electrolysis of hot sodium chloride brine. This salt has recently supplanted potassium chlorate to a considerable extent in medicine and is also used in making dyes, matches, and high explosives.

The production of sodium chlorate in the United States in 1918 is withheld, as there were only two producers. The figures have, however, been combined with those for sodium perborate which also could not be published separately. The total production of these two salts was 2,413 short tons, valued at $1,004,250, against 2,915 tons, valued at $1,333,426, in 1917.

Imports of sodium chlorate in 1918 were 22 short tons, a slight increase over those of 1917.

Sodium chlorate was produced in 1918 by the North American Chemical Co., Bay City, Mich., and the Oldbury Electro Chemical Co., Niagara Falls, N. Y.

SODIUM CHLORIDE (COMMON SALT).

The production and utilization of sodium chloride (NaCl) are given in full in the chapter on salt in Mineral Resources by R. W. Stone,[1] of the United States Geological Survey, whose figures for the production in 1918 are 2,830,600 short tons in brine, 1,683,941 short tons of rock salt, and 2,724,203 short tons of evaporated salt, valued at $1,245,265, $5,684,661, and $20,010,435, respectively. The corresponding figures for 1917 are shown in the table on page 161.

The known production of sodium carbonate from salt and limestone and that of caustic soda from salt by electrolysis show that approximately 2,260,000 short tons of sodium chloride was used for making

[1] Salt, bromine, and calcium chloride: U. S. Geol. Survey Mineral Resources, 1918, pt. 2, pp. 119–121, 1919.

sodium carbonate in the United States in 1918, and that about 165,000 tons of salt was electrolyzed for the production of caustic soda, chlorine, and other products in 1918. In addition, at least 85,000 short tons must have been used in making hydrochloric acid and other sodium compounds.

SODIUM CHROMATE.

(See Sodium bichromate, p. 169.)

SODIUM CYANIDE.

Since the war created a scarcity of potassium cyanide sodium cyanide has been largely substituted for it in the cyanide process of recovering gold and silver from their ores. Sodium cyanide is manufactured by the Niagara Electro Chemical Co., Niagara Falls, N. Y.

In order not to reveal the production of individual firms the figures for the production of sodium cyanide in 1917 have been combined with those for sodium iodide and sodium peroxide. The combined production of these salts in 1918 was 9,086 short tons, valued at $5,427,240, compared with 9,694 short tons, valued at $6,133,000, in 1917.

Analysts are accustomed to determine only the cyanide radical in cyanides, as their value depends on the cyanogen content, but it has long been customary to report the cyanogen as potassium cyanide. As pure potassium cyanide contains 40 per cent and sodium cyanide 53 per cent of cyanogen it follows that sodium cyanide may be reported as carrying more than 100 per cent of potassium cyanide. This also allows very impure sodium cyanide to be sold as 97 or 98 per cent potassium cyanide, but, needless to say, the potassium salt is not now largely used. Recently sodium cyanide has been selling on the basis of its actual sodium cyanide content, the highest grade being 96 to 98 per cent sodium cyanide (NaCN), or cyanogen 51 to 52 per cent. The old "98 per cent KCN" used to run about 39 per cent of cyanogen. Four pounds of sodium cyanide are therefore chemically equivalent as a solvent to about 5 pounds of the old "KCN."

Sodium cyanide is widely used as a solvent of the precious metals in metallurgy and in electroplating, and also as a source of hydrocyanic acid for fumigation in orchards where gaseous hydrocyanic acid is applied as an insecticide to individual trees, which are covered with tents during the process. The great production of gold from low-grade properties in the last two decades, beginning in the Transvaal and extending all over the world is largely due to the "cyanide process." The effective solution in the cyanide process contains usually only about 0.20 per cent of sodium cyanide. Sodium cyanide is also used in case hardening and in synthesizing organic acids.

Sodium cyanide may be made from ferrocyanide or sulphocyanide obtained from gas works, coke works, or beet-sugar waste. It results, for example, from heating sodium ferrocyanide with sodium according to the reaction $Na_4Fe(CN)_6 + 2Na = 6NaCN + Fe$. The process is carried out in iron crucibles, the melted cyanide being

filtered through spongy iron by means of compressed air. When made in this way the only impurities are small quantities of sodium cyanate, sodium carbonate, and sodium hydroxide.[1]

The Castner process of making sodium cyanide consists in heating together at the proper temperature sodium and ammonia, and finally also charcoal in furnaces especially designed for that purpose. The intermediate products are sodamide ($NaNH_2$) and sodium cyanamide (Na_2CN_2). The final result is summarized by the equation $2NH_3+2Na+2C=2NaCN+3H_2$.

Sodium cyanide may be made by heating commercial calcium cyanamide ($CaCN_2+C$) for a few minutes with common salt at about 940° C. out of contact with air and then quickly cooling the mixture. The product contains from 20 to 30 per cent of sodium cyanide and may be used directly for the extraction of gold.

The manufacture of cyanides directly from atmospheric nitrogen has been the subject of much study and now offers promise of commercial development. The Bucher process consists in heating soda ash and powdered coke with iron ore in a furnace through which air is passed. This process is now under investigation by Government agencies.

United States patent 1256272, issued February 12, 1918, to P. A. Starke, describes a method of making cyanides by passing natural gas and ammonia over a mixture of soda ash, magnesia, and iron heated to 400–800°. The manufacture of cyanides from calcium cyanamide is described in United States patents 1277989 and 1277900, issued to H. Freeman, September 3, 1918. According to patent 1262057, issued April 7, 1918, to A. Kaufman, a briquet with fused outer coating of sodium cyanide is effective in the preservation of sodium cyanide.

A paper on the war and the nitrogen industry by W. S. Landis appeared in Chemical and Metallurgical Engineering, volume 19, page 828, 1918.

SODIUM FERROCYANIDE.

Sodium ferrocyanide, yellow prussiate of sodium ($Na_4Fe(CN)_6.10H_2O$), is used in making certain blue colors, such as Prussian blue, Chinese blue, and Paris blue, which are employed extensively in dyeing textiles and in making paint and printing ink. Practically all ferrocyanide is now made from material obtained in purifying coal gas. Such material is mixed with lime, and the soluble calcium ferrocyanide is leached out and subsequently converted into sodium ferrocyanide by treatment with sodium carbonate.

Before the war a considerable quantity of this salt was imported from England and Germany, but the restriction of imports during the war resulted in a greatly increased domestic production, owing to the decreased importation of ferrocyanide, as well as to the supplanting of potassium ferrocyanide by sodium ferrocyanide on account of the scarcity of potash.

The quantity of sodium ferrocyanide marketed in the United States in 1918 was 4,525 short tons, valued at $2,690,110. This was a small increase in value over the corresponding figures for 1917,

[1] Martin, Geoffrey, and Barbour, William, Industrial nitrogen compounds and explosives, p. 72, New York, 1917.

which were 4,173 short tons, valued at $2,577,667. The domestic production in both 1917 and 1918 was much larger than that of any previous year. Imports of sodium ferrocyanide have been decreasing each year since 1914, when they amounted to 1,148 short tons, valued at $171,834.

Prices obtained for sodium ferrocyanide in 1918 were notably higher than the average of 1917, but they have since fallen considerably below those of 1917. It is understood that the producers in this country are now in a position to supply all domestic requirements.

In British patent 109254, issued to E. V. Espenhahn, July 25, 1917, it is proposed to wash gases containing cyanogen compounds with a hot concentrated solution of sodium carbonate containing ferrous sulphide or ferrous sodium ferrocyanide in suspension. The washing liquor after separating the insoluble matter is cooled to crystallize $Na_4Fe(CN)_6.10H_2O$.

In United States patent 1252741, issued January 8, 1918, to A. R. Tillinghast the gases are scrubbed with a suspension of ferrous carbonate in sodium carbonate, the resulting solution is treated with milk of lime to convert insoluble ferrocyanides into soluble ferrocyanides and the sodium ferrocyanide is crystallized after filtration from insoluble matter. United States patent 1252742 describes the treatment of the mother liquor with ferrous sulphate to form a fresh absorbing medium.

Sodium ferrocyanide was manufactured in 1918 by

Citizens Gas Co., Indianapolis, Ind.
Henry Bower Chemical Manufacturing Co., Philadelphia, Pa.
Morris Herrman & Co., Port Elizabeth, N. J.
Penman-Littlehales Co., Syracuse, N. Y.
Portland Gas & Coke Co., Portland, Oreg.
Seattle Lighting Co., Seattle, Wash.
Semet-Solvay Co., Syracuse, N. Y.
Worcester Gas Light Co., Worcester, Mass.

SODIUM FLUORIDE.

Sodium fluoride (NaF) is made by treating cryolite with NaOH, the NaF being sparingly soluble. It may also be made from hydrofluoric acid and soda ash. This salt is used in making enamels, and as a flux and insecticide. Sodium fluosilicate or silicofluoride is also used in making enamels. United States patent 1247619, issued November 27, 1918, to J. S. Beckett, describes the manufacture of sodium fluosilicate from phosphate rock containing fluorides.

The reported production of sodium fluoride, acid sodium fluoride, and sodium fluosilicate in the United States in 1918 amounted to 1,228 short tons, valued at $281,264, compared with 1,424 short tons, valued at $397,305, in 1917.

Sodium fluoride is produced by the General Chemical Co., New York, N. Y., the Harshaw, Fuller & Goodwin Co., 720 Electric Building, Cleveland, Ohio, and John C. Wiarda & Co., Brooklyn, N. Y. The Harshaw, Fuller & Goodwin Co. also makes acid sodium fluoride. The production of sodium fluosilicate in 1918 was reported by the Baugh Chemical Co., 25 South Calvert Street, Baltimore, Md., the Davison Chemical Co., Baltimore, Md., the Virginia-Carolina Chemical Co., Richmond, Va., and the Armour Fertilizer Works, Chicago, Ill.

SODIUM HYDROXIDE.

Sodium hydroxide, or caustic soda (NaOH; theoretically Na_2O 77.48 per cent, H_2O 22.52 per cent), is a base and not a salt of sodium.

Production.—The total production of caustic soda in the United States in 1918, as reported by the producers, and not including that made in soap works, amounted to 513,363 short tons, valued at $31,854,470, as compared with 488,056 short tons, valued at $29,402,689, in 1917. Of this quantity about 85 per cent, or 434,156 short tons, valued at $26,776,579, represents sales, the remainder, 79,207 short tons, valued at $5,077,891, was consumed by the producers in their own plants.

The production of caustic soda may be further classified according to the method of manufacture. In 1918 about 72 per cent of the production, or 370,591 short tons, was made from sodium carbonate and lime, and 28 per cent, or 142,772 short tons, was made by the electrolysis of sodium chloride. The average value of that made in the first way was $59 a ton, as reported by the producers, and of that made by electrolysis $64 a ton. Electrolytic caustic, however, varies widely in value according to its purity, method of preparation, and the purpose for which it is made.

Imports and exports.—The imports of caustic soda for consumption in the United States dropped from 146,236 pounds, valued at $17,773 in 1917, to only 2,002 pounds, valued at $193, in 1918, according to statistics compiled by the Department of Commerce. The exports in 1918 were 48,689 short tons, valued at $5,602,813, of which Japan, Brazil, Canada, Cuba, and Argentina received the largest quantities, in decreasing order of quantity exported to each. This compares with exports for the last six months of 1917 of 44,997 short tons, valued at $5,832,598, going principally to Japan, Italy, Brazil, Argentina, Canada, Mexico, and France.

The need of other countries for caustic soda heretofore imported is leading to many proposals for the construction of plants.

A plant has been constructed by the Brunner, Mond Co. (Ltd.), of Canada, for the manufacture of soda ash and caustic soda at Amherstburg, Ontario, where salt and limestone occur close together. Caustic soda is now manufactured by the electrolytic process by the Canadian Salt Co. at its works at Sandwich, Ontario.

It is understood that plants for the electrolytic production of caustic soda have been begun recently in Peru, Brazil, China, and Japan. The Brazilian Government has offered pecuniary assistance to the first three firms beginning operations.

Manufacture.—Sodium hydroxide may be made from the black ash liquor of the Leblanc process (p. 173) by treating the diluted liquor with lime at a boiling temperature. Calcium carbonate settles out and the resulting lye is purified by evaporation and removal of the salts which separate as the concentration proceeds until finally fused NaOH is obtained. The last step in the purification consists in the addition of a very little niter, which decomposes sulphides and cyanides. Sodium hydroxide is made in exactly the same way from sodium carbonate prepared by the ammonia process, but it does not then require the treatment with niter. The spent causticizing mud, after being thoroughly separated from the liquor, is generally treated in rotary kilns to recover the lime.

Many pulp and paper mills make sodium hydroxide from lime and soda ash in their own plant. The recovery of the soda ash has been described under sodium carbonate (p. 174).

At the mill of the Kingsport Pulp Corporation, Kingsport, Tenn., a continuous process of causticizing soda ash with lime was tried over a period of several months. It was stated that the total cost of producing caustic soda, exclusive of the cost of raw materials, was approximately 47 cents a short ton of 100 per cent sodium hydroxide, with labor at 30 cents an hour and power at 2 cents a kilowatt hour.

Much caustic soda is now made by the electrolysis of sodium chloride in solution, and many types of cells have been used or proposed to keep the anodic and cathodic products separated. Chlorine is produced at the anode and either sodium hydroxide, sodium carbonate, or an alloy, or an amalgam of sodium at the cathode. For some purposes the anodic and cathodic products of electrolysis are allowed to mix and the resulting solution is used directly in bleaching. The anodes are generally of graphite. The chlorine produced at the anode is either liquefied or converted into bleaching powder, sulphur monochloride, carbon tetrachloride, chloroform, or other chlorine compounds used in making dyes, war gases, benzoic acid, and other compounds. Electrolytic caustic soda can compete with the Solvay soda only by utilizing the chlorine in some way.

In the Castner-Kellner process the cathode is mercury, and the cell consists of three compartments so arranged that a weak sodium amalgam is no sooner formed in the middle compartment containing a solution of salt than it passes into one of the outer compartments containing water, which reacts with the amalgam under the influence of the electric current to form a dilute solution of sodium hydroxide.

The Townsend cell relies on the separation of caustic soda solution by gravity through a heavy oil, into which drops of the caustic solution are carried from the cathode by means of a slight flow of the brine through the diaphragm adjacent to the cathode.

The Allen-Moore cell relies on a circulation of the brine. The framework of these cells is of concrete and the construction permits a change of diaphragms without dismantling the whole cell. The voltage drop per cell varies from 3.2 to 3.5 volts and a current density of about 42 amperes per square foot is employed

The Nelson cell maintains an atmosphere of steam in the cathode compartment which regulates the flow of brine and decreases the resistance of the cell.

The Hargreaves-Bird cell, which has been mentioned under sodium carbonate (p. 174) consists of a diaphragm immersed on the anode side, the diaphragm and cathode being exposed to an atmosphere of steam and carbon dioxide whereby the sodium salts are washed off in the form of sodium carbonate solution. The efficiency of this cell is said to be greater when producing sodium carbonate than when producing caustic soda and the diaphragms last longer

Other cells in use or under investigation are the Billeter, Wheeler, and Gibbs cells.

The Loewig process of making sodium hydroxide consists in heating soda ash with ferric oxide to form sodium ferrite and carbon dioxide, which is completely volatilized. The sodium ferrite is afterward decomposed by water to from a concentrated solution of sodium hydroxide, specific gravity 1.49, and iron oxide, which is used over again.

A powder for generating caustic soda and adapted for transfer or storage in boxes or bags has been described; it consists of a mixture of dry slacked lime with from three to five parts of dry sodium carbonate.

Uses.—Sodium hydroxide is used in large quantities in making soap, lye, and pulp or fiber for making paper. It is also used in mercerizing cotton, in purifying oils and fats, in refining petroleum, reclaiming rubber, in making dyes and phenol (which is used in the manufacture of the picrates for explosives), in making pigments, cleaning metals for electroplating, and in the chemical trade.

The need of the Government for caustic soda in 1917 and 1918 led to a regulation of exports by means of licenses. All restrictions were finally removed after the armistice was signed, however, and the quantity of caustic soda remaining on hand was so small that its disposition was without effect on the market.

Producers.—The following list gives the producers of caustic soda in 1918, exclusive of soap makers:

Baltimore Copper Smelting & Rolling Co., Baltimore, Md.
Brown & Co., 404 Commercial Street, Portland, Me.
Champion Fibre Co., Canton, N. C.
Columbia Chemical Co., Pittsburgh, Pa.
Diamond Alkali Co., Pittsburgh, Pa.
Dill & Collins Co., Sixth and Cherry Streets, Philadelphia, Pa.
Dow Chemical Co., Midland, Mich.
E. I. du Pont de Nemours & Co., Wilmington, Del.
Eastern Electro-Chemical Co., Bangor, Me.
Edgewood Arsenal, Edgewood, Md.
Fields Point Manufacturing Co., Box 4, Edgewood Station, Providence, R. I.
Great Western Electro-Chemical Co., Holbrook Building, San Francisco, Calif.
Gulf Refining Co., Port Arthur, Tex.
Hamersley Manufacturing Co., Garfield, N. J.
Hooker Electro-Chemical Co., Niagara Falls, N. Y.
Huron Milling Co., Harbor Beach, Mich.
Isco Chemical Co., Niagara Falls, N. Y.
Jessup & Moore Paper Co., Philadelphia, Pa.
Kimberly-Clark Co., Neenah, Wis.
Mathieson Alkali Works, Providence, R. I.
Mead Pulp & Paper Co., Dayton, Ohio.
Miami Paper Co., West Carrollton, Ohio.
Michigan Alkali Co., Detroit, Mich.
Michigan Electro-Chemical Co., Menominee, Mich.
Niagara Alkali Co., Niagara Falls, N. Y.
Niagara Smelting Corporation, Niagara Falls, N. Y.
Oxford Paper Co., 200 Fifth Street, New York, N. Y.
Pennsylvania Salt Manufacturing Co., Philadelphia, Pa.
Penobscot Chemical Fibre Co., 49 Federal Street, Boston, Mass.
Republic Chemical Co., Pittsburgh, Pa.
Rub No More Co., Dorenger Avenue, Fort Wayne, Ind.
Solvay Process Co., Syracuse, N. Y.
Vulcan Detinning Co., Sewaren, N. J.
Warner Chemical Co., 52 Vanderbilt Avenue, New York, N. Y.
Warner-Klipstein Chemical Co., 52 Vanderbilt Avenue, New York, N. Y.
S. D. Warren Co., Boston, Mass.
West Virginia Pulp & Paper Co., 200 Fifth Avenue, New York, N. Y.

SODIUM IODIDE.

Sodium iodide (NaI) may be prepared in several ways, as, for example, from caustic soda and iodine. It is used in photography, in analytical chemistry, and in medicine, especially for making solutions of iodine. It is said that this salt may be employed in

medicine with fully as favorable results as are obtained from potassium iodide.

The production of sodium iodide in the United States in 1918 has been given with that of sodium cyanide and sodium peroxide. It is manufactured by McKesson & Robbins (Inc.), 91 Fulton Street, New York, N. Y.; the Mallinckrodt Chemical Works, St. Louis, Mo.; the Powers-Weightman-Rosengarten Co., Philadelphia, Pa., and E. R. Squibb & Sons, New York, N. Y.

SODIUM NITRATE.

Data on the occurrence and production of sodium nitrate ($NaNO_3$) are given in a previous volume of Mineral Resources.[1] As is well known, most of the sodium nitrate used in the United States is imported from South America, principally from Chile. The imports for consumption in 1916 were 1,275,962 short tons, valued at $38,131,364; in 1917 1,728,390 short tons, valued at $60,727,100; and in 1918 2,069,379 short tons, valued at $90,216,935, according to records of the Department of Commerce.

Refined sodium nitrate was produced in 1918 by E. R. Squibb & Sons, New York, N. Y., and the Mallinckrodt Chemical Works, St. Louis, Mo.

Many samples of nitrate-bearing material have been examined by the United States Geological Survey from time to time, but, although the percentages of nitrate have at times been very promising, the material has so far either not been found in quantity in any given locality or it has been found to be so widely disseminated in lavas or tuffs as to make its successful commercial treatment doubtful.

SODIUM NITRITE.

Sodium nitrite ($NaNO_2$) is made by heating sodium nitrate with lead. The product is extracted with water and the solution is allowed to crystallize, when anhydrous sodium nitrite separates. It is used in making coal-tar dyes and as a chemical reagent. The production reported for 1918 was 1,701 short tons, valued at $609,779, compared with 861 short tons, valued at $840,145, in 1917.

The imports for consumption in 1918 were 1,429 short tons, valued at $289,182, compared with 4,384 tons, valued at $349,111, in 1917.

Sodium nitrite was manufactured in 1918 by the following firms:

Atlas Powder Co., Wilmington, Del.
E. I. du Pont de Nemours & Co., Wilmington, Del.
Harshaw-Fuller & Goodwin Co., 720 Electric Building, Cleveland, Ohio.
Merrimac Chemical Co., 148 State Street, Boston, Mass.
Semet-Solvay Co., Syracuse, N. Y.

The American Nitrogen Products Co., Seattle, Wash., did not report any sodium nitrite in 1918, but stated that experimental work was being carried on.

SODIUM PERCARBONATE.

United States patent 1263258, issued April 16, 1918, to O. Liebknecht, claims that sodium percarbonate is precipitated from a solution containing sodium carbonate and hydrogen peroxide by the addition of a large quantity of sodium chloride.

No production of this salt was reported to the United States Geological Survey for 1918.

[1] Phalen, W. C., Potash salts: U. S. Geol. Survey Mineral Resources, 1914, pt. 2, p. 18, 1916.

SODIUM PERBORATE.

Sodium perborate, which is made by suspending borax in a solution of sodium carbonate that is being electrolyzed, is used in laundry work, in bleaching cotton and linen, and for hygienic purposes. It is an oxidizing agent. According to the mode of preparation, sodium perborate has the formula $Na_2B_4O_8.10H_2O$ or $NaBO_3.4H_2O$. The addition of sulphuric acid to a solution of sodium perborate sets free hydrogen peroxide, or the same result can be obtained by merely heating the solution; in fact, in bleaching, sodium phosphate is often used with sodium perborate to maintain an alkaline solution.

Figures for the production of this salt have been combined with those for the production of sodium chlorate, the total for 1918 being 2,413 short tons, valued at $1,004,250, compared with 2,915 short tons, valued at $1,333,426, in 1917.

In United States patent 1268369, dated June 4, 1918, and issued to O. Liebknecht, it is claimed that a mixture of sal soda and sodium perborate accelerates the formation of more perborate in the electrolysis of an alkaline solution containing borax.

Sodium perborate was manufactured in 1918 by Roessler & Hasslacher Chemical Co., 100 William Street, New York, N. Y.

SODIUM PERMANGANATE.

Sodium permanganate ($NaMnO_4$) is made by the electrolytic oxidation of sodium manganate. It is used where potassium permanganate was formerly employed. The production of this salt, which was made in 1918 by the Kalbfleisch Corporation, Brooklyn, N. Y., is included with miscellaneous salts. Some sodium permanganate is made as an intermediate product in the process of manufacturing potassium permanganate.

SODIUM PEROXIDE.

Sodium peroxide is manufactured by the Niagara Electro Chemical Co., Niagara Falls, N. Y. It is made by burning metallic sodium in an excess of air or oxygen. It is used in chemical analysis, especially in decomposing pyrite and chromite, and in bleaching, also for generating oxygen in hospitals, submarines, and mine-rescue apparatus, and in making hydrogen peroxide. When pressed into blocks with a little nickel sulphate, copper sulphate, or potassium permanganate, sodium peroxide may be used to generate oxygen merely through the action of water.

In order not to reveal the output of single producers the production of sodium peroxide in 1918 has been added to that of sodium cyanide and sodium iodide, the combined figures being 9,086 short tons, valued at $5,427,240, compared with 9,694 short tons, valued at $6,133,000, in 1917.

SODIUM PHOSPHATE.

Sodium phosphate ($Na_2HPO_4.12H_2O$) is one of several different phosphates, all of which are derived originally from phosphate rock. The rock is first treated with sulphuric acid, the solution of phosphoric acid thus obtained is separated from the insoluble calcium sulphate and neutralized with soda ash, and this solution is allowed to crystallize.

Sodium phosphate is used in the textile industry, as a water softener, in making baking powder, and in the pharmaceutical trade.

Sodium phosphate was manufactured in 1918 by the following firms:

Armour Fertilizer Works, Chicago, Ill.
Bowker Chemical Co., 2 Rector Street, New York, N. Y.
Burns Manufacturing Co., 15 Beaver Street, New York, N. Y.
Grasselli Chemical Co., Cleveland, Ohio.
Victor Chemical Works, Fisher Building, Chicago, Ill.
Warner Chemical Co., 52 Vanderbilt Avenue, New York, N. Y.

Trisodium phosphate was manufactured by Bowker Chemical Co., Grasselli Chemical Co., and Burns Manufacturing Co.

The total production of all varieties of sodium phosphate, including monosodium phosphate, disodium phosphate, and trisodium phosphate, in the United States in 1918 amounted to 15,620 short tons, valued at $1,427,947. The following table contains such figures as are available for the annual production of sodium phosphate to date:

Sodium phosphate produced in the United States, 1899–1918.[a]

	Quantity (short tons).	Value.		Quantity (short tons).	Value.
1899	2,340	$155,989	1914	15,397	$853,528
1904	4,830	244,373	1917	13,305	711,283
1909	12,290	540,282	1918	15,620	1,427,947

[a] The figures for the years 1899, 1904, 1909, and 1914 are from Chemicals and allied industries: Census of Manufactures, p. 18, U. S. Dept. Commerce Bur. Census, 1918.

SODIUM SILICATE.

Sodium silicate or water glass, as manufactured commercially, is not a definite chemical compound. The bulk of the commercial product is of 1.38 specific gravity, but it ranges from 1.34 to 1.91. The molecular ratio of SiO_2 to Na_2O in these different grades varies from about 1 to 4, being lowest in the most concentrated solutions.

The production of sodium silicate for the calendar year 1918 amounted to 317,161 short tons, valued at $5,870,973, which compares with 254,011 short tons, valued at $3,317,547, in 1917. The last previously reported production was that given by the Bureau of the Census for 1914, which amounted to 169,049 short tons, valued at $1,648,854, a great advance over all previous years. The price of the 40° B. strength f. o. b. tank cars rose from $12 a ton during the first quarter of 1917 to $17 in the last quarter, and advanced to $19 by March, 1918. Recent prices for the 60° B. strength have been steady between 3 and 4 cents a pound.

Imports of sodium silicate have decreased each year since 1915. Exports, however, during the last six months of 1917 amounted to 7,275 short tons, valued at $216,828, and in 1918 they amounted to 14,125 short tons, valued at $404,796, according to figures furnished by the Department of Commerce.

The original use of sodium silicate in this country, and the use still requiring the largest quantity, is as an ingredient of household and laundry soap. Other important uses are as an adhesive in the manufacture of corrugated and combined fiber shipping cases, wall

board, veneer panels, asbestos products, and in sealing shipping cases; as a binder in abrasive wheels, and in acid-proof and heat-resisting cements; in sizing barrels, grease-proofing paper board, paper sizing, egg preserving, silk weighting, and as a boiler compound.

Sodium silicate was manufactured by the following firms in 1918:

L. Feuchtwanger, Little Ferry, N. J.
Frohman Chemical Co., Sandusky, Ohio.
General Chemical Co., New York, N. Y.
Grasselli Chemical Co., Cleveland, Ohio.
Mechling Bros. Manufacturing Co., Camden, N. J.
Philadelphia Quartz Co., 121 Third Street south, Philadelphia, Pa.
Philadelphia Quartz Co. of California, Berkeley, Calif.
Procter & Gamble Co., Cincinnati, Ohio.
Valley Chemical & Manufacturing Co., 111 North Market Street, Chicago, Ill.

SODIUM SULPHATE.

SALT CAKE.

Sodium sulphate (Na_2SO_4) is obtained in large quantities in the manufacture of hydrochloric acid from sodium chloride, either with the aid of niter cake, of sulphuric acid, or by Hargreave's process from sulphur dioxide, air, and steam. The product is generally termed "salt cake."

The salt cake marketed in the United States in 1918 amounted to 141,054 short tons, valued at $2,844,897, a slight decrease in quantity and value from the output for 1917. The Bureau of the Census reported an output of 90,442 tons of salt cake, valued at $841,887 for the year 1914.

Uses.—Sodium sulphate as salt cake is used in making plate glass, window glass, and bottles. Glassmaker's salt cake should be very low in iron, sulphuric acid, sodium chloride, and calcium sulphate. Hargreave's process for making salt cake is said to produce a practically iron-free product, but this process is not generally used in the United States. The same result is obtained by making salt cake in lead pans, which requires considerable skill, or by preparing Glauber's salt from crude salt cake. Sodium sulphate as salt cake is also used in making paper pulp by the sulphate process and in making sodium sulphide, and a small quantity is used by aniline manufacturers and in making ultramarine.

It is claimed that sodium sulphate can be used instead of sodium carbonate in the soda wood pulp industry. In this process of making pulp the waste liquors containing sodium carbonate and carbonaceous matter are evaporated and the residue is finally calcined to recover sodium carbonate. If sodium sulphate is added to the waste liquors it is converted by calcination into sodium sulphide, which is said to have the same action on pulp as caustic soda. But if the proper quantity of limestone is added before calcining it appears that sodium carbonate would be the principal product obtained by extraction. This could then be causticized as usual.

Various patents have been granted for making sodium sulphate from sodium chloride with the simultaneous production of other compounds. Thus, H. B. Kipper in United States patent 1255020, issued January 29, 1918, uses a mixture of ferric oxide and sodium chloride in the presence of sulphur dioxide and oxygen, forming sodium sulphate and chlorine. L. P. Bassett uses clay, gypsum, and salt to form sodium sulphate and cement.

Manufacturers.—The following firms produced sodium sulphate as salt cake in 1918:

American Steel & Wire Co., 502 Western Reserve Building, Cleveland, Ohio.
Ault & Wiborg Co., Cincinnati, Ohio.
Butterworth-Judson Corporation, 61 Broadway, New York, N. Y.
Consolidated Chemical Co., McKittrick, Calif.
Contact Process Co., 351 Abbott Road, Buffalo, N. Y.
E. I. du Pont de Nemours & Co., Wilmington, Del.
General Chemical Co., New York, N. Y.
Grasselli Chemical Co., Cleveland, Ohio.
Kalbfleisch Corporation, 31 Union Square west, New York, N. Y.
Charles Lennig & Co., Philadelphia, Pa.
Merrimac Chemical Co., 148 State Street, Boston, Mass.
Monsanto Chemical Works, St. Louis, Mo.
Mutual Chemical Co. of America, New York, N. Y.
National Zinc Co., Kansas City, Kans.
Naugatuck Chemical Co., Elm Street, Naugatuck, Conn.
Pennsylvania Salt Manufacturing Co., Philadelphia, Pa.
Powers-Weightman-Rosengarten Co., Philadelphia, Pa.
Stauffer Chemical Co., 624 California Street, San Francisco, Calif.
Western Chemical Manufacturing Co., West Bryant Avenue and South Pecos Street, Denver, Colo.

GLAUBER'S SALT.

The hydrated salt obtained by recrystallization below 32.4° C. ($Na_2SO_4.10H_2O$), Glauber's salt, is in demand where purity is an essential. It is used in dyeing, in tanning, in the textile industry as a mordant assistant, and in medicine. It is, however, an expensive form in which to transport sodium sulphate. Much Glauber's salt is made from impure salt cake, which after heating to remove the excess water is sold as "glassmaker's salt cake."

The Glauber's salt marketed in 1918 amounted to 50,715 short tons, valued at $1,041,070.

The following list gives the manufacturers of Glauber's salt in 1918:

Atlantic Carbonic Co., 258 Third Street, Chelsea, Mass.
Burns Manufacturing Co., 15 Beaver Street, New York, N. Y.
Central Chemical Co., foot of Chapel Street, Newark, N. J.
Columbus Crystal Co., 15 Arch Street, Newark, N. J.
E. I. du Pont de Nemours & Co., Wilmington, Del.
Durex Chemical Corporation, 320 Fifth Avenue, New York, N. Y.
General Chemical Co., New York, N. Y.
Grasselli Chemical Co., Cleveland, Ohio.
Iowa Soda Products Co., Detroit, Mich.
Kalbfleisch Corporation, 31 Union Square west, New York, N. Y.
Kimberly-Clark Co., Neenah, Wis.
Charles Lennig & Co. (Inc.), Philadelphia, Pa.
Mechling Bros. Manufacturing Co., Camden, N. J.
Merrimac Chemical Co., 148 State Street, Boston, Mass.
National Zinc Co., Kansas City, Kans.
Pennsylvania Salt Manufacturing Co., Philadelphia, Pa.
Powers-Weightman-Rosengarten Co., Philadelphia, Pa.
E. R. Squibb & Sons, 60 Beekman Street, New York, N. Y.

NITER CAKE.

Niter cake, the residual product in the manufacture of nitric acid from sodium nitrate and sulphuric acid, differs from salt cake in containing acid sodium sulphate ($NaHSO_4$) in varying quantity. Manufacturers report either the percentage of bisulphate or the percentage of sulphuric acid in the product. Pure sodium bisulphate carries 40.8 per cent of sulphuric acid and commercial grades carry from 25 to 35 per cent of sulphuric acid, which corresponds to 61 to 86 per cent of sodium bisulphate.

The quantity of niter cake made in the United States in 1918 was very large, owing to the demand for nitric acid for making explosives, and much of the niter cake was not marketed.

The marketed production amounted to 143,155 short tons, valued at $595,660.

This quantity of niter cake accounts for only about 72,000 tons of sodium nitrate, whereas the Department of Commerce reports the importation of 2,069,379 short tons of sodium nitrate from Chile in 1918. The difference in these figures may be partly accounted for by the consumption of niter cake in making hydrochloric acid and sodium sulphide, but in any case a very large quantity represents either niter cake not utilized or sodium nitrate that went into fertilizers or was stored for future use. Very few manufacturers of fertilizers making sulphuric acid have reported the production of niter cake, which, if made, is doubtless consumed in their own works.

Niter cake may be prepared in a friable form by adding sodium carbonate or any substance that evolves a gas to melted niter cake.

Niter cake is used as a substitute for sulphuric acid for many purposes, as in metal pickling, in absorbing ammonia, in making paper, sodium sulphate, and fertilizers. Experiments have shown that superphosphates containing 15 per cent of available P_2O_5 can be readily produced from Florida pebble phosphate by mixing the finely ground material with niter cake, the reaction taking place without applying heat. Too much sodium sulphate in fertilizers, however, is considered objectionable by some authorities.

The following firms manufactured niter cake in 1918:

Aetna Explosives Co., New York, N. Y.
American Steel Wire Co. of New Jersey, 502 Western Reserve Building, Cleveland, Ohio.
American Zinc & Chemical Co., Oliver Building, Pittsburgh, Pa.
Armour Fertilizer Works, Chicago, Ill.
Atlas Powder Co., Wilmington, Del.
Ault & Wiborg Co., Cincinnati, Ohio.

NATURAL SODIUM SULPHATE.

Some of the analyses on pages 176–178 indicate that sodium sulphate is an abundant constitutent of surface salts in several localities, especially in Wyoming, Utah, and Nevada. Sodium sulphate is found in many soils in regions of deficient rainfall, being known as

white alkali, in contrast to sodium carbonate, which is known as black alkali on account of its corrosive action on vegetation. The exact proportion of white alkali that may exist in a soil without being positively deleterious is a matter of disagreement among soil experts, but small quantities are certainly not fatal to many crops.

Hydrated sodium sulphate ($Na_2SO_4.10H_2O$) decreases markedly in solubility with falling temperature, so that it deposits from many lakes containing strong brine in cold weather. Gilbert[1] says that this salt is deposited from the Great Salt Lake in cold weather and thrown up in heaps on the shore. Experiments by the writer have shown that the separation begins at 1°C. In Sevier Lake, Utah, which is at times entirely dry, the salts have been alternately dissolved and redeposited, with the result, as noted by Gilbert, that the sodium sulphate is chiefly found near the center and sodium chloride near the margin of the lake. Some "lakes" in western Saskatchewan, Canada, are reported to contain very large quantities of nearly pure Glauber's salt, and this salt, which is known mineralogically as mirabilite, as well as the anhydrous salt, thenardite, has been reported in considerable abundance at several localities in the Western States.

Natural sodium sulphate has been utilized at various times in small quantity. It seems as if greater use could be made of it. When it occurs mixed with sodium carbonate the mixture may be regarded as having been carried nearly through the Leblanc process, so that instead of attempting to separate the two salts it might be possible to transform the sulphate into carbonate by calcination with limestone and coal producing soda ash, a large proportion of soda ash being already present in the natural salts. Moreover, the natural mixture might be used directly in making glass.

John D. Gill and associates, Cheyenne, Wyo., and the Consolidated Chemical Co., McKittrick, Calif., reported the production of natural sodium sulphate in 1918. Natural sodium sulphate has also been produced commercially at Sweetwater Valley, Wyo., and the salt has been refined by C. W. Beers, 1188 West Thirtieth Street, Los Angeles, Calif.

In 1885 Weeks[2] described natural sodium carbonate and sulphate near Laramie, Wyo., and the manufacture of caustic soda from these materials.

The Southern Chemical Co., Mills Building, El Paso, Tex., conducted experimental work in 1918 on the production of anhydrous sodium sulphate from their deposit of the natural salt near Valmont, N. Mex. Commodity rates have been granted to shipments of this material.

SODIUM SULPHIDE.

Sodium sulphide (Na_2S), may be formed by heating salt cake with coal, but it is more economical to make it from niter cake, sodium chloride, and coal, with the incidental production of hydrochloric acid. After lixiviation the product is obtained as crystals ($Na_2S.9H_2O$), carrying about 32 per cent of sodium sulphide. A more concentrated salt may be prepared by evaporating until the temperature reaches about 160° C. and then allowing the liquor to cool. The product thus obtained carries about 62 per cent of sodium sulphide.

[1] Gilbert, G. K., U. S. Geol. Survey Mon. 1, p. 253, 1890.
[2] Weeks, J. D., Glass materials: U. S. Geol. Survey Mineral Resources, 1885, pp. 551–552, 1886.

For preservation and transportation a more nearly anhydrous salt is desirable. The General Chemical Co. sells a product known as "chipped" sodium sulphide.

Sodium sulphide is used in dyeing, in cleaning fabrics, in making the sulphur dyes and other dyes, in tanning, for removing hair from skins, in sulphurizing oxidized lead and copper ores preparatory to flotation, and in precipitating silver from cyanide solutions. A dilute solution of it has also been used as a solvent for gold in the hydrometallurgy of gold ores, the gold being later precipitated by copper or an aluminum-zinc alloy, as described by F. Wartenweiler.[1]

The production of sodium sulphide in the United States in 1918 amounted to 43,490 short tons, valued at $2,293,304. This material includes both the 32 and 62 per cent grades, the larger part, however, being the 62 per cent grade. The quantity is slightly less than that reported in 1917, 49,494 short tons, which included more of the 32 per cent grade. The value is greater than that of any previous year for which figures are available.

The production of sodium sulphide given by the Bureau of the Census for 1914 was 20,263 tons, valued at $516,644, and 7,673 tons, valued at $206,450, for 1909.

In 1918 there was imported for consumption 112,821 pounds of sodium sulphide, valued at $4,673, according to the figures of the Department of Commerce, whereas the imports in 1917 were 288,292 pounds, valued at $5,104.

The following list gives the manufacturers of sodium sulphide in 1918:

Ault & Wiborg Co., Cincinnati, Ohio.
Contact Process Co., 351 Abbott Road, Buffalo, N. Y.
Charles Cooper & Co., Newark, N. J.
Durex Chemical Corporation, 320 Fifth Avenue, New York, N. Y.

Merrimac Chemical Co., 148 State Street, Boston, Mass.
Rollin Chemical Co., South Charleston, W. Va.

SODIUM TETRABORATE (BORAX).

COMPOSITION.

Sodium tetraborate ($Na_2B_4O_7.10H_2O$), commonly called borax and by some sodium biborate, is both a mineral and a manufactured product. Crude natural borax is known as tincal. It is found in San Bernardino County, Calif., associated with gypsum, anhydrite, thenardite, glauberite, hanksite, halite, and trona; also in several other counties in California; in saline lakes and playas in Nevada and Oregon; and in the hot springs of the Yellowstone Park. The present source of refined borax in the United States, however, is the mineral colemanite ($Ca_2B_6O_{11}.5H_2O$), from which borax is manufactured by treatment with sodium carbonate.

The formula of borax given above represents the hydrate formed at ordinary temperature. The crystals effloresce, however, when exposed to the air and lose in all $5H_2O$ below 100° C., the sixth molecule at 100°, the seventh and eighth at 130°, the ninth at 150°, and the tenth at 160° and above, the last molecule being held so tenaciously that 300° is desirable to insure complete desiccation, according to J. Hoff-

[1] Inst. Mining Met. Bull., vol. 166, 15 pp., 1918.

man.[1] The very careful experiments of Smith and Van Haagen [2] show that even borax glass still retains about 0.2 per cent of moisture under ordinary conditions.

PRODUCTION AND PRICES.

The quantity of borax sold in the United States in 1918 was 26,673 short tons, valued at $3,909,565. This salt was produced by the Pacific Coast Borax Co., 100 William Street, New York, which produces both borax and boric acid, as do also Charles Pfizer & Co., 81 Maiden Lane, New York City; and the Thorkildsen-Mather Co., Forty-fifth and Elizabeth streets, Chicago, Ill.

According to quotations in the trade journals, the price of borax was steady throughout 1918, ranging from 6½ to 10 cents a pound, but most of the time holding close to 8 cents.

PATENTS.

In United States patent 1259717, issued to H. Blumenberg, March 19, 1919, it is proposed to treat calcareous boron ore with nitric acid to form boric acid and calcium nitrate. Patent 1259718 seeks the recovery of nitric acid from the calcium nitrate.

USES.

Borax on fusion dissolves the oxides of the metals, forming characteristically colored glasses that are useful in blowpipe tests. Fully a third of the borax consumed annually in this country, however, is used in the manufacture of enamels or porcelain-like coatings for such objects as bathtubs, kitchen sinks, and cooking utensils. Borax is also used as a flux in the melting and purification of the precious metals, in decomposing chromite, in making glass, as a preservative, and as a cleansing agent.

SOURCES OF DOMESTIC BORAX.

So far as known to the writer, domestic borax was derived entirely in 1918 from the mineral colemanite, which is produced from a few mines in southern and southeastern California, but the American Trona Corporation was reported as expecting to produce from 20 to 30 tons of refined borax daily in 1919 from the water of Searles Lake. The latest information is that production from this source is under way. The development represents an entirely new feature in the domestic borax industry.

According to reports received by the United States Geological Survey the production of crude boron ore in California in 1918 was 88,794 tons, valued at $2,263,230, as against 108,875 tons, valued at $3,609,632, in 1917.

A map showing the location of borax deposits in the western United States will be found in Mineral Resources for 1916, Part II, page 389.

Some new deposits of boron ores have been discovered at Muroc, Kern County, Calif. The Stauffer Chemical Co. continued prospecting on the north side of Frazer Mountain, in Ventura County, but without material results up to June, 1919.[3] No ore was mined by this company in 1918.

---

[1] Chem. Industry, vol. 39, p. 411, 1916.
[2] Smith, E. F., and Van Haagen, W. K., The atomatic weights of boron and fluorine: Carnegie Inst. Washington Pub. 267, 1918.
[3] Yale, C. G. Personal communication.

Most of the boron ore mined in California is concentrated before being shipped to the borax producers. At the Lang property of the Sterling Borax Co. this treatment includes heating, which drives off most of the water, disintegrates the colemanite, and causes the admixed clay to gather into lumps that are easily separated. The concentrated ore runs from 30 to 45 per cent of boric oxide. In 1917 the Pacific Coast Borax Co. put in Wilfley concentrators to work over old tailings and reported a good recovery. The concentrated ore was valued at $0.97 to $1 a unit of B_2O_3.

IMPORTS.

Borax is no longer imported into the United States and practically no boron ores, but 259,096 pounds of boric acid, valued at $26,436, was imported in 1918. This is the smallest quantity, with the exception of 232,545 pounds in 1912, for many years, the value, however, being larger than that for any year as far back as 1906, when 986,021 pounds, valued at $33,200, was imported.

FOREIGN BORATES.

An excellent bibliography of papers relating to borax and borates, by H. S. Gale, will be found in the chapter on borax in Mineral Resources for 1913. The descriptions given below are intended to refer chiefly to the deposits that are now being actively worked in various parts of the world.

Chile.—The borate deposits of Chile are near the salars or near the western Cordillera, at relatively high altitudes of the Andes in the Provinces of Tarapaca, Antofagasta, and Atacama. They have been described by several investigators [1] and are usually considered as having been derived originally from volcanic sources and later carried in solution to their present positions. One of the most important deposits is that of Lake Ascotan, near the station of Cevollar, in Antofagasta, first discovered in 1859 and at present operated by Borax Consolidated (Ltd.), London. The ore is sodium-calcium borate. Although periodic attempts have been made to convert the calcium borate in the various Chilean deposits into either borax or boric acid it is understood that at present the material is exported as calcium borate, which after drying or calcining carries more than 40 per cent B_2O_3. Import duties into the principal European countries favor the introduction of unrefined material as contrasted with half-refined or manufactured material.

Other South American countries.—Borates are found in the salars of northwestern Argentina, southwestern Bolivia, and southern Peru, just as in those of Chile, and are occasionally unaccompanied by the usual salts of the salars. The ore from these deposits has been carried to the various shipping points mostly on mule back.

Germany.—Several boron minerals are found in the Stassfurt deposits and have been worked for boric acid, but no statistics are available as to the production from this source.

Italy.—The fumaroles of Tuscany are well known as a source of boric acid and illustrate the association of boric acid with volcanism. They were described by R. Nasini in the report of the Sixth International Congress of Applied Chemistry, Rome, 1906. Italy has been an important exporter of boric acid for many years.

[1] See Clarke, F. W., The data of geochemistry: U. S. Geol. Survey Bull. 616, p. 249, 1916.

Turkey.—The mineral pandermite ($2CaO.3B_2O_3.3H_2O$), which is found as a stratum underlying gypsum in Asiatic Turkey near the Sea of Marmora, has long been shipped to Europe as a source of borax and boric acid.

Russia.—On the peninsula of Kertch, near the Sea of Azov, Crimea, borax occurs among the erupted substances of the so-called mud volcanoes. It effloresces on the surface of the dried mud, more or less mixed with salt and soda, but so far as known has never been utilized commercially.

Tibet.—Crude borax, called tincal, is transported overland on sheep back from the high regions of the Himalayas to Calcutta.

SODIUM THIOSULPHATE.

Sodium thiosulphate, which is very generally known in the trade as sodium hyposulphite or "hypo," is made by treating sodium sulphite with sulphur, or from milk of lime, sulphur, and soda ash, or from waste materials containing sulphur, such as Leblanc tank waste.

The principal use of this salt is in the leather trade. It is also used in the textile industry for removing the last traces of chlorine from bleached fabrics, and in bleaching wool, straw, oils, ivory, and bones (as a source of sulphur dioxide), and in dyeing, in analytical chemistry, and in the manufacture of dyes, paper, and mordants. Its use in photography as a fixing agent depends on its solvent action on silver salts which have not been affected by light.

United States patent 1270150, issued June 18, 1918, to A. K. Gyzander, proposes to make sodium thiosulphate by treating sodium sulphite with hydrogen under pressure of 100 atmospheres for 24 hours.

The production of this salt in the United States in 1918 was 26,868 short tons, valued at $1,051,623.

Sodium thiosulphate was manufactured in 1918 by

General Chemical Co., New York, N. Y.
Grasselli Chemical Co., Cleveland, Ohio.
Charles Lennig & Co. (Inc.), Philadelphia, Pa.
Mechling Bros. Manufacturing Co., Camden, N. J.

MISCELLANEOUS SODIUM COMPOUNDS.

A scattered production of various sodium salts, chiefly organic chemicals used in analytical chemistry, photography, and medicine, was reported in 1918, which can not be given in detail without revealing figures of individual producers. The list includes sodium citrate, sodium phenolsulphonate, sodium salicylate, sodium oxalate, sodium arsenate, sodium arsenite, sodium bitartrate, sodium tartrate, sodium hypochlorite or chlorinated soda solution, sodium formate, sodium succinate, sodium permanganate, and sodium sulpho carbolate.

The total production of these salts reported amounts to 381 short tons, valued at $1,122,552.

The producers reporting include

Heyden Chemical Works, New York, N. Y.
Mallinckrodt Chemical Works, St. Louis, Mo.
Semet-Solvay Co., Syracuse, N. Y.
E. R. Squibb & Sons, New York N. Y.

PHOSPHATE ROCK.[1]

By Ralph W. Stone.

PRODUCTION.

PHOSPHATE ROCK SOLD.

The phosphate rock marketed in the United States in 1918 was 2,490,760 long tons, valued at $8,214,463. As compared with the production in 1917, which amounted to 2,584,287 long tons, valued at $7,771,084, there was a decrease in quantity of 93,527 tons, or 3.6 per cent, and an increase in value of $443,379, or 5.7 per cent. In this report the value of domestic material means selling value f. o. b. mines.

Phosphate rock sold in the United States, 1909–1918.

Year.	Quantity (long tons).	Value.	Year.	Quantity (long tons).	Value.
1909	2,338,264	$10,796,456	1914	2,734,043	$9,608,041
1910	2,654,988	10,917,000	1915	1,835,667	5,413,449
1911	3,053,279	11,900,693	1916	1,982,385	5,896,993
1912	2,973,332	11,675,774	1917	2,584,287	7,771,084
1913	3,111,221	11,796,231	1918	2,490,760	8,214,463

PHOSPHATE ROCK MINED.

The quantity of phosphate rock mined in any year is not the same as that sold, for the quantity in stock at the mines at the end of each year is variable. The quantity mined in 1918 was 2,284,245 long tons, a decrease of 567,641 tons, or 19.9 per cent from the output of 1917. The decrease in production was general. In Florida the decrease was 443,247 tons, or 19 per cent, with 28 plants in operation, 9 less than in 1917; in South Carolina 11,868 tons, or 26 per cent, with 3 producing plants, as in 1917; in Tennessee 108,160 tons, or 23.8 per cent, with 21 plants in operation, 2 less than in 1917; and in the Western States 4,479 tons, or 27 per cent, with 3 producers instead of 4.

STOCKS.

Stocks on hand at the end of 1918 were about 1,127,000 tons, a decrease of about 260,000 tons, or 19 per cent, from the stocks at the close of 1917. The stocks on hand in Florida were reported to be about 1,046,000 tons and in Tennessee about 61,000 tons. This decrease in stocks was due to the fact that in Florida, South Carolina, Tennessee, and Kentucky more rock was sold than was mined.

[1] The statistical tables in this chapter, except those showing imports and exports, were prepared by Miss L. M. Jones, and the tables of imports and exports were compiled from the records of the Bureau of Foreign and Domestic Commerce by J. A. Dorsey, both of the United States Geological Survey.

PRODUCTION BY STATES.

OUTPUT AND PRICE.

In 1918 there was a small increase in quantity of phosphate rock sold in Florida and South Carolina, but a larger decrease in quantity sold in Tennessee and the Western States, making a net decrease for the country. On the other hand, the average price per ton increased in all States, the percentages of increase being 9 in Florida, 7 in South Carolina, 24 in Tennessee, and 27 in the Western States. The increase in average price per ton in the whole country was from $3.01 in 1917 to $3.30 in 1918, or nearly 10 per cent.

Phosphate rock sold in the United States, 1917–18.

[a] Includes several thousand tons of brown rock from Kentucky.
[b] Includes, 1917: Idaho, Utah, and Wyoming; 1918: Idaho and Utah.

FLORIDA.

In 1918 Florida, the leading State in the production of phosphate rock, marketed 2,067,230 long tons, valued at $6,090,106, or 83 per cent of all the phosphate rock sold in the United States. This was an increase of 44,631 tons, or 2.2 per cent, over the shipments of 1917, but the total nevertheless was nearly 500,000 tons less than that of 1913, the last year of normal production.

Hard-rock phosphate, which was the variety most exported before the war, decreased in output from nearly 500,000 tons in 1913 to less than 20,000 tons in 1917. It seems to have reached the limit of depressed output in 1917 for the quantity sold in 1918 was 62,000 tons, an increase which suggests perhaps a preparation on the part of the producers of hard-rock phosphate to begin exportation in large quantity as soon as opportunity offers.

Soft-rock phosphate is now produced by three companies in Florida and the figures can be shown separately for the first time. This could not be done formerly without revealing confidential informa-

tion. The output in 1918 was somewhat greater than in 1917. The quantity of land pebble produced in 1918 was 7,144 tons less than in 1917, a very small quantity considering that the total output in each of these years was approximately 2,000,000 tons. There was a great decrease in the quantity of phosphate reported by the original producers as sold as ground rock, only 12,329 tons, in comparison with 27,690 tons in 1917.

The average price per ton of hard rock was $6.08, as compared with $6.10 in 1913. The average price per ton of soft rock increased from $12.40 in 1917 to $17.66 in 1918, but the latter figure may be too high, because freight rates have apparently been included in the selling prices reported. The average price of land pebble increased from $2.65 in 1917 to $2.79 in 1918.

Florida phosphate rock sold in 1913–1918.

[a] Several thousand tons of soft rock included with hard rock.
[b] Includes a small quantity of river pebble.

SOUTH CAROLINA.

The phosphate rock mined in South Carolina was land rock only and although the quantity mined was 11,868 tons, or 26 per cent, less than in 1917, the quantity sold was an increase of 3,555 tons, or 11 per cent. Stocks on hand at the close of the year, however, decreased from 20,918 in 1917 to 17,551 in 1918. The average price per ton increased from $4.14 to $4.45.

South Carolina phosphate rock sold in 1913–1918.

Year.	Quantity (long tons).	Value.	Year.	Quantity (long tons).	Value.
1913	109,333	$440,588	1916	53,047	$211,125
1914	106,919	415,039	1917	33,485	138,482
1915	83,460	310,850	1918	37,040	164,650

TENNESSEE AND KENTUCKY.

The quantity of phosphate rock sold in Tennessee and Kentucky in 1918 was 374,535 tons, valued at $1,917,546, a decrease of nearly 27 per cent in quantity and a slight decrease in value from 1917. Nearly all this rock was mined in Tennessee, and all the decrease must ascribed to that State, for the production in Kentucky, which can not be shown separately because there was only one operator, was considerably greater in both quantity and value than in 1917. About 33,000 tons of Tennessee phosphate was reported by producers as sold as ground rock, a considerable decrease from 48,000 tons so reported in 1917. The average price per ton of Tennessee-Kentucky rock increased from $4.14 in 1917 to $5.12. In 1918 the average price per ton of brown rock was $5.26 and of blue rock $4.15, as compared with $4.29 for brown rock and $3.12 for blue rock in 1917. By far the larger quantity of phosphate mined in Tennessee was brown rock, of which more than 300,000 tons were sold. The exact figures can not be given without revealing confidential information concerning the production of Tennessee blue rock and the single producer in Kentucky.

[a] Blue rock is included with brown rock.
[b] Includes some blue and white rock and a very small quantity of rock from Arkansas.
[c] Includes a small quantity of brown rock from Kentucky.

WESTERN STATES.

The phosphate rock industry in the Western States showed a decrease of 21 per cent in 1918, the shipments falling from 15,096 tons to 11,955 tons. There was an increase in total value however, from $41,756, or an average of $2.77 per ton, to $42,161, or $3.53 per ton, making the total value of the product greater than in any previous year. There were 3 producers in 1918 instead of 4, operations at Cokeville, Wyo., having been discontinued.

Western States phosphate rock sold in 1913–1918.

Year.	Quantity (long tons).	Value.	Year.	Quantity (long tons).	Value.
1913	5,053	$18,167	1916	1,703	$5,350

[a] Exports.

[b] Apatite.

IMPORTS OF FERTILIZER MATERIALS.

The fertilizer materials imported into the United States in 1918 comprised many compounds containing phosphorus, nitrogen, and potash. Those containing phosphorus include bone ash, guano, basic slag, and phosphate rock. The potash fertilizers include various potash salts, kainite, manure salts, and double manure salts. The nitrogen compounds are chiefly calcium cyanamid, nitrates, and ammonium salts.

The quantity of calcium cyanamid, or lime nitrogen, used in the United States has increased from 5,000 tons in 1911 to 47,268 tons in 1917, but fell off slightly in 1918 to 45,209 tons. It is a powder containing 20 to 22 per cent of nitrogen which is manufactured at Niagara Falls, Canada, and is used by more than 300 manufacturers of fertilizer in the United States.

Fertilizers imported and entered for consumption in the United States, 1914–1918.[a]

The preceding table, compiled from records of the Bureau of Foreign and Domestic Commerce, does not include all the material imported into the United States which goes into the fertilizers manufactured and sold in this country. To the materials listed in the table should be added potash salts, and a considerable quantity of sodium nitrate. The production of potash salts in the United States is described in another chapter in Mineral Resources.

EXPORTS.

Since 1913, when more than 1,300,000 tons of phosphate rock was exported, the quantity leaving the United States has steadily decreased until in 1918 it was only 143,455 tons, a little more than one-tenth of the exports in 1913. The following table, compiled from reports of the Bureau of Foreign and Domestic Commerce, shows exports of phosphate rock in the last three years:

Phosphate rock exported from the United States, 1916–1918.[a]

Kind.	1916		1917		1918	
	Quantity (long tons).	Value.	Quantity (long tons).	Value.	Quantity (long tons).	Value.
Phosphate rock, ground or unground, not acidulated:						
High-grade rock	28,631	$286,948	12,403	$113,392	57,771	$445,419

1917	2,584,287	166,358	6
1918	2,490,760	143,455	6

DISTRIBUTION AND CHARACTER OF DEPOSITS.

UNITED STATES.

FLORIDA.

Florida phosphate deposits are the most extensively developed in the United States. Four classes are mined—hard-rock, land-pebble, river-pebble, and soft-rock phosphate.

Hard-rock phosphate.—The hard-rock phosphate occurs as boulders and pebbles in a soft matrix of phosphatic sands and clays and other material, the whole resting on a limestone of lower Oligocene Age. The boulder deposits occur in the form of pockets of irregular size, ranging from a few square yards to several acres in area. The boulders themselves vary in size from a few inches to several feet in diameter. The phosphatic content of this class of deposit ranges from less than 10 to more than 30 per cent of the mass, the marketable product being not more than 15 per cent of the total mined material. The rock itself runs as high as 85 per cent in tricalcium phosphate and is sold on a guaranty of 77 per cent tricalcium phosphate.

The workable deposits are very irregular. At some places they are at the surface, elsewhere they may lie so deep as to be economically unworkable; equally promising drill records may indicate in one case an extensive deposit and in another a single boulder or pocket. There is no rule to which these hard-rock deposits agree in regard to depth from surface, thickness, lateral extent, quantity, and quality.

Hard-rock phosphate occurs over a considerable area which extends with varying width for about 100 miles in the western part of central peninsular Florida. The area extends from the southern part of Columbia and Suwanee counties through the western part of Alachua and Marion counties, and the eastern part of Levy, Citrus, and Hernando counties into the northern part of Pasco County. There is also a limited area in Lafayette, Taylor, and Jefferson counties. It must be understood that this is the general area in which the deposits occur, the workable deposits themselves being very much less than the area outlined.

There were four shippers of hard-rock phosphate in Florida in 1918 who had a total production of about 62,000 tons, or about one-eighth of the normal production prior to the European war. A large number of hard-rock mines were idle, much of the rock shipped being drawn from stocks on hand.

In mining hard-rock phosphate the overburden is usually removed by horsepower scrapers or by picks and shovels, although the removal in some places is by steam shovel and hydraulic. Mining is then by hand work with shovels or by steam shovel if the rock is above ground-water level; mining below ground-water level is by steam dredge.

The phosphate is loaded on small cars and raised from the pit by inclined cable railway to a washer where it passes through a grizzly. After passing a log washer it goes through cylindrical screens and is washed at the same time to remove sand and clay. The coarser material is sorted by hand on a revolving circular table. Hard rock is usually dried by stacking with wood under a shed and burning the wood; at some mines it has been dried by passing through a heated rotary metal cylinder. When cool it is ready for shipment.

Land-pebble phosphate.—The pebble phosphate is composed of rounded or subangular pebbles up to the size of a walnut embedded in a matrix of sand, clay, and soft phosphate. The pebble deposits usually show more or less natural sorting, with alternating layers of coarse and fine material. The color of the pebbles ranges from light gray to blue or black. The land-pebble deposits are in beds of varying thickness, but they are much more regular than the hard rock, and for that reason cost less to mine. The workable deposits range from a few feet to 25 feet, and probably average 10 to 12 feet thick.

Land pebble is found resting on upper Oligocene limestone and marls, and overlain by sand. The thickness of the overburden ranges from a few feet to 40 feet and probably averages more than 15 feet.

The land-pebble deposits occur in an oval area 40 miles long and 30 miles wide, lying east of Tampa, in the eastern part of Hillsboro and the western part of Polk counties. The extent of the deposits is difficult to determine because the sands are not distinctive and the gravel is exposed at few places except in mines and pits. The principal centers of land-pebble phosphate mining are between Mulberry and Fort Meade in Polk County. Twelve producers in 1918 shipped 1,996,847 long tons of land-pebble phosphate, valued at $5,565,928.

Although the land-pebble deposit underlies a considerable area, it is mined at comparatively few places. Several factors determine the location of a mine. The thickness of the overburden must be considered, the quantity and quality of the phosphate economically available, and the distance from a railroad. Obviously the character as well as the thickness of the overlying sand affect the commercial utilization of a deposit. Soft sand can be removed by hydraulic but indurated sand may have to be blasted and then removed by steam shovel, which is so expensive that if the overburden is thick the phosphate can not be economically recovered unless it too is thick and several acres in extent.

Removal of the overburden from a deposit of land pebble is done by hydraulic or steam shovel. The pebble is then hydraulicked into a sump from which it is raised by centrifugal pumps and conveyed through pipes to the washer. The washers are much the same type as those used in cleaning hard-rock phosphate. From log washers the rock passes through revolving cylindrical screens, and is dried in inclined rotary kilns, from which it goes to the storage bins and is ready for shipment.

The phosphate content of the marketed product generally ranges from 60 to 75 per cent of tricalcium phosphate.

River-pebble phosphate.—Deposits of pebble-phosphate accumulated on river bars are found on several tributaries of St. Johns River and on Peace River. The pebbles have rounded outlines produced by mechanical abrasion and range from small granules to those 2 inches or more in diameter. The average diameter is less than an inch. River-pebble phosphate is usually stained dark by organic matter, but the discoloration is surficial. Fragments of bones and teeth of sharks and other animals are common in these deposits. In some places so many shells of marine organisms are mixed with the pebbles that mining is impracticable.

The pebbles are found in a matrix of sand and sandy clay of various colors. The deposits form parts of extensive accumulation of detritus in the valleys of some of the streams flowing through regions

containing other types of phosphate. The quality of river-pebble phosphate is lower than that of hard rock or land-pebble phosphate, the composition ranging from 55 to 65 per cent tricalcium phosphate. This type of deposit has been mined principally in De Soto County along Peace River near Mulberry, Arcadia, Hull, and Fort Ogden. A few thousand tons were taken in 1911–1914, but there has been no production since 1914. Because of the character of the deposits and their very small extent it is not to be expected that there will ever be a large production of river-pebble phosphate.

Soft-rock phosphate.—Soft-rock phosphate forms a large portion of the matrix of hard-rock phosphate deposits and more or less of the matrix in land-pebble deposits. It is in fine powder or in soft masses that crumble to dust when dry but are very plastic when wet. It occurs also in small pockets in the limestone of the Vicksburg group, and in large bodies south of Greer, northwest of Ocala, and southwest of Richland. Large quantities of soft phosphate are mined with hard-rock phosphate, but in washing to remove the matrix the soft phosphate goes with the sand and clay to the waste heap. This constitutes a very considerable annual loss of phosphoric acid. In 1918 more than 8,000 tons of soft phosphate were mined and sold from Hernando, Levy, and Marion counties.

Further information on phosphate in Florida can be found in annual reports in Mineral Resources of the United States, in United States Geological Survey Bulletin 604 (Phosphate deposits of Florida) and in the fifth and seventh annual reports of the Florida State Geological Survey.

SOUTH CAROLINA.

The phosphate deposits of South Carolina are confined to a seaboard zone, most of it less than 30 miles wide, which extends from Beaufort on the south to 20 miles north of Charleston. Charleston is the center of the phosphate and fertilizer industry. The phosphate occurs in two forms, as land rock and as river rock. The land rock occurs in a more or less irregular bed which represents the undisturbed Edisto marl. It has a maximum thickness of 30 inches, but averages probably between 8 and 13 inches, and is in many places absent. It generally consists of an uneven or jagged mass of honeycombed rock. In places the cavities which are probably due to solution are as much as 4 inches in diameter. Much of the material is light yellowish brown and is soft and chalky.

The river rock probably consists in part of the original phosphatized Edisto marl and in part of fragments derived from the land deposits and concentrated on the river bottom, the whole deposit having been been worked over more or less by river action. It occurs generally in loose rounded fragments accumulated on the river bottoms. As would be expected in a river deposit, this reworked material is very irregular in distribution.

A tract of land rock to be mined is first thoroughly prospected. The overburden along a strip 20 feet wide is then removed by steam shovel and the phosphate taken up either by pick and shovel or by clamshell excavator. It is loaded on flat cars and sent to the washer. Hand mining can be done only where the overburden in less than 8 feet, and as the more accessible deposits have been exhausted this method is no longer used. Steam pumps or levees are necessary to keep water out of the excavations while mining is being carried on.

River rock has not been reported as produced since 1910. In most of the more recent mining of river rock the clamshell dredge was used; one bucket dredge was also employed. The limit of depth of this work was about 50 feet of water.

The phosphate delivered from the dredge is mixed with sand and clay and must be washed and dried before it is ready to ship. Probably less than half of the material delivered from the flat cars to the hopper of the bucket elevator is phosphate. The conveyor dumps the rock into a crusher where it is broken and partly washed. The fragments are then delivered to the lower end of a metal cylindrical washer through which the material is carried up against a stream of water by a series of spiral plates. The washed rock is conveyed to wet bins and subsequently dried by being piled on ricks of wood, the burning of which drives off the moisture. It is estimated that by the present method about 20 per cent of the phosphate in finely pulverized form is lost in washing and goes to the waste dump.

In 1918 three phosphate plants in South Carolina were operated. The commercial rock varies greatly in phosphate content, but at no place does it contain more than 64 per cent tricalcium phosphate in the washed unburned condition. It is probable that the general average for the South Carolina area approximates 58 per cent tricalcium phosphate. In much of the rock the phosphate content is as low as 55 or 53 per cent. Rock of this grade competes with difficulty with the higher grade rock from Florida and Tennessee.

The production of the South Carolina field has fallen off greatly within the last few years. No river rock has been mined since 1910. There is no prospect that the industry will increase considerably in the near future, although the phosphate in the area is far from exhausted. It is estimated that there are probably at least 5,000,000 tons of 60 per cent phosphate still in the ground and improved machinery may at some time in the future make these deposits workable. That can scarcely be, however, until the high-grade and cheaply-mined phosphate in Florida and Tennessee is nearly exhausted.

TENNESSEE.

The phosphate deposits in Tennessee, which are classed as brown, blue, and white rock, are in the middle part of the State. Low-grade phosphate rock occurs in Johnson County in extreme eastern Tennessee, but it is not mined. The brown rock comes from Maury, Giles, Hickman, Lewis, and Sumner counties, and the blue rock from Lewis and Maury counties. White rock is found chiefly in Perry and Decatur counties, but none has been marketed since 1908.

Brown-rock phosphate occurs in plates of varying thickness and also as a porous material which disintegrates to phosphate sand. The two forms are commonly associated. It occurs in beds known as collar deposits and blanket deposits. Collar deposits are found where the horizontal phosphatic limestone bed outcrops on the slope of a steep hill, and the blanket deposits occur near the surface in broad, more nearly level areas. The deposits are of secondary origin and therefore are irregular in thickness.

Brown-rock phosphate has been dug in the Mount Pleasant region in Maury County, near Wales, Giles County, and on lower Swan Creek. The overlying clay is stripped by drag-line excavator,

hydraulic jet, or horse scraper, and the phosphate rock which occurs in irregular fashion is dug by hand and hauled to the washers in dump carts or by dinky tram.

At the washer the rock is crushed, run through log washers, and dried either by open wood fire or by rotary kiln. The brown rock is sold under guaranty of 70 to 80 per cent tricalcium phosphate.

Blue-rock phosphate is of sedimentary origin and is mixed with clay, sand, and gravel. The strata range in thickness from a few inches to 2 or 3 feet, and occur along Leatherwood Creek in the western part of Maury County, south and east of Centerville and on both sides of Swan Creek in Hickman County, in the eastern part of Lewis County, and in Perry and Wayne counties. The rock contains 30 to 85 per cent tricalcium phosphate, but rock having the higher content does not occur in large quantities.

Blue-rock phosphate is a tough granular rock like limestone and is mined by the room and pillar method, as it occurs in flat-lying beds under good cover. The mined rock is hauled on tram cars to the crushing and drying plant where it is prepared for shipment. Washing is not necessary, and at some plants the rock is crushed and marketed without drying.

KENTUCKY.

Phosphate deposits in Kentucky are of the brown-rock type and occur in the form of loose-rock blanket deposits near the surface. The workable deposits vary from 1 to 6 feet in thickness and are very irregular. They originated from concentration in the weathering of phosphatic limestone. The cover of clay and soil varies from 2 to 10 feet. The only mine operated recently is near Wallace in Woodford County, which is the locus of the central Kentucky field. Phosphate rock occurs also near Lexington, Fayette County, and in Franklin, Scott, Clark, and Jessamine counties. Phosphate has been produced in recent years by one firm only and the output therefore can not be revealed.

ARKANSAS.

The phosphate deposits that have been developed in Arkansas are located in northwestern Independence County, along Lafferty Creek. The deposits extend over a considerable area in the north-central part of the State, and the phosphate horizon has been recognized in Stone, Izard, Searcy, Marion, Baxter, and Newton counties. This does not mean that phosphate rock will be found in all these counties of sufficiently high grade to work with profit wherever its horizon outcrops, but that an intelligent conception of its geologic position may enable it to be more readily found and prospected. In the area in which it is found only sedimentary rocks are exposed at the surface. The names and relative positions of these rocks with the phosphate-bearing formation are given below:

Carboniferous: Boone limestone (including St. Joe limestone member).
Devonian: Chattanooga shale (including Sylamore sandstone member).
Silurian: St. Clair limestone.
Ordovician:
Cason shale (phosphate horizon).
Fernvale limestone. } "Polk Bayou" limestone.
Kimmswick limestone. }
Izard limestone.

The phosphatic beds themselves vary in character, ranging from those that are brown, sandy, and of low grade to those that on fresh surfaces are bluish gray, apparently without sand, and of uniform texture and color. Manganese ore is so commonly associated with the phosphate that it is a good guide in prospecting for it. In the areas where the development has taken place the phosphate rock occurs in two layers, only the upper one of which is worked, the lower being considered of too low grade for exploitation. The upper bed is a compact, homogeneous light-gray rock, with a specific gravity of about 3. The following section of the deposit on the hillslope between Lafferty Creek and White River, Independence County, shows the relations of the phosphate rock. As will be seen from the section its aggregate thickness is from 8½ to 10 feet.

Section containing phosphate beds.[1]

	Ft.	in.
St. Clair limestone.

Low-grade manganiferous iron ore	1	3
Green to dark-clay shale	1	2
High-grade phosphate	4½–6	
Manganiferous iron ore		2
Low-grade phosphate	4	
Polk Bayou limestone.		

Analyses made in the Survey laboratory show the best ore to run from 56 to more than 71 per cent in bone phosphate.

A small production was reported in 1915 and previous years, but none since 1915. Most of the phosphate removed from the Arkansas area is obtained in much the same manner as the blue rock in Tennessee. The rock is first stripped and mined around the hillslope until the overburden makes this method too expensive. Drifts are then run into the hill, and the rock is blasted out and hauled to the mouth of the drift for shipment. Some of the rock is dried by being piled upon ricks of wood, which are then burned. Fuel is abundant, and burning has the advantage of reducing freight charges.

UTAH.

The phosphate deposits of Utah occur at two horizons, in the upper Mississippian and in the Permian. The upper Mississippian deposits are in Rich and Cache counties. Beds near Logan, Cache County, are from 6 inches to 2½ feet thick and carry from 31 to 70 per cent of tricalcium phosphate. In Laketown Canyon, Rich County, there is a phosphate zone nearly 7 feet thick, and some of the material contains as much as 81.7 per cent of tricalcium phosphate. In the Oquirrh Range, 50 miles southwest of Salt Lake City, there is a deposit of phosphate rock that carries 67 to 75 per cent of tricalcium phosphate. The quantity available in these districts has not been determined.

In the Uinta region the beds of phosphate are 1 foot to 6 feet thick, and some contain 70 per cent of tricalcium phosphate. In the Ogden region some of the beds contain 39 to 62 per cent of tricalcium phosphate, and in Weber Canyon a single 13-foot bed has an average content of 46.1 per cent. In the Woodruff and Crawford mountains

[1] Purdue, A. H., Developed phosphate deposits of northeastern Arkansas: U. S. Geol. Survey Bull. 315, p. 469, 1907.

the main bed is usually 5 to 6 feet thick and contains 70 per cent of tricalcium phosphate. This area contains about 96,750,000 long tons of high-grade phosphate rock. No estimate can yet be made of the quantity in the other regions.

The great body of the western phosphate occurs in Permian rocks, and rocks of this age are widely distributed through northeastern Utah. The Permian phosphate deposits are in Summit, Wasatch, Duchesne, and Uinta counties, along the northern and southern flanks of the Uinta Mountains, and to the north in Weber, Morgan, and Rich counties. They occur largely in public land which is at the disposal of the United States Government. On July 31, 1919, the area in Utah withdrawn as lands containing deposits of phosphate amounted to 302,465 acres.

The phosphate bed mined near Randolph, Utah,[1] is 4 to 6 feet thick, but is divided into two parts by a lean layer 2 to 7 inches thick, which separates about a foot of the high-grade ore at the bottom of the bed from the upper part. The dip of the bed is 50°. A main crosscut tunnel is driven to the bed and a drift turned along it both ways. Raises are put up from the drift and the ore stoped down. The upper bench is taken out first and the chutes and entries are cleared. Then the lean parting is mined out and put on the waste dump. When the entries have been cleaned again the lower bench is mined. The drift and stope is advanced again on the upper part of the bed, and the operation repeated. The rock is drilled by hand, blasted, and falls down the stopes into chutes at the bottom of the raises. It is trammed out of the mine in small cars running on a light track.

IDAHO.

The known phosphate lands of Idaho lie in the southeastern part of the State, in Bear Lake, Bannock, Bingham, Bonneville, and Fremont counties. The Government has reserved 1,015,717 acres in Idaho as workable phosphate land, to which must be added 4,080 acres of officially classified phosphate land in the Fort Hall Indian Reservation. Idaho appears to contain the largest body of high-grade phosphate rock in the western field. In the Georgetown Canyon region there are three commercially workable beds, from 3 to 6 feet thick, that carry 72.9 to 82.3 per cent of tricalcium phosphate. The main bed throughout the Idaho district averages 5 or 6 feet in thickness and carries about 70 per cent of tricalcium phosphate. Estimates based on detailed studies indicate that the areas examined probably contain 5,200,000,000 long tons of tricalcium phosphate. These estimates include chiefly the main bed, which contains high-grade rock carrying 65 per cent or more of tricalcium phosphate; they do not include the thinner beds of high-grade rock nor the great body of low-grade material. Large areas of phosphate land have not yet been examined. Rock phosphate is mined and shipped from Montpelier and Paris, Bear Lake County.

The formation in which the phosphate occurs has been upturned and folded in the mountain-making processes, and the phosphate bed almost everywhere dips at a steep angle. The first mining of phosphate rock near Montpelier, Idaho, where the bed dips steeply with

[1] Stone, R. W., Phosphate rock industry of the United States: Rock Products, Oct. 8, 1918.

the slope of the hill, was done by blasting from the ledge and rolling the rock down the incline to a stock pile. It was loaded into wagons and hauled to the railroad for shipment to the Pacific coast, where it was used for making superphosphate. This simple method of mining, however, is not applicable for long. With further development and increased production from a steeply dipping bed underground mining is employed.

The phosphate bed at the Waterloo mine near Montpelier, Idaho, is 5 feet thick and dips about 30°. Extraction of the rock was begun by an open cut, and quarrying covered an area about 200 feet square. Then tunnels were driven below the quarry to cut the bed well below the surface. According to a personal letter from W. F. Kett, of San Francisco Chemical Co., the development consists of crosscut tunnels to the deposit, then drifts along its course. Raises are run from the drifts 100 to 150 feet apart. Small pillars are left to protect the raises, and the ground between them is stoped. The raises are equipped with steel-bottomed chutes and the ore goes by gravity from the face of the stope down the chutes to mine cars in the drifts. The stopes are drawn clean, propped with heavy timbers, and left to cave. The pillars along the raises are robbed last. The rock is not very hard, and drilling is done with geared coal augers worked by hand. This method removes practically all the phosphate rock, which is carried from working face to stock bins by gravity.

Underground mining is employed at Paris, Idaho, to extract the phosphate rock which occurs in a steeply dipping bed striking north. Where the phosphate crosses the deep valley of Paris Creek a crosscut tunnel has been driven. According to a letter from Lewis A. Jeffs, president of the Western Phosphate Mining & Manufacturing Co., the crosscut reaches the bed at about 90 feet from the portal, with approximately 50 feet of stoping ground overhead at this point. A drift follows the bed for approximately 600 feet in a southerly direction, and in August, 1918, was advancing about 5 feet a day. The drift gains about 25 feet of backs or stoping ground for every 100 feet run along the bed. Raises and chutes are put in along the drift and the ore is stoped in the usual manner.

WYOMING.

The phosphate lands of Wyoming are in their western part contiguous to those of Idaho, from which they extend eastward through several mountain ranges in Uinta, Lincoln, and Fremont counties as far as the Owl Creek Mountains. The Government has reserved in Wyoming as phosphate land 998,592 acres, and has officially classified as phosphate land 20,576 acres in the Wind River Indian Reservation, a total of 1,182,816 acres of phosphate land in this State.

The richest deposit reported in northwestern Wyoming is in the canyon of Snake River, 3 miles below the mouth of Fall River. Here, besides the main bed, 9 feet thick, a random sample from which yielded 68.5 per cent of tricalcium phosphate, there are several beds from 2 to 12 feet thick, carrying from 20 to 60 per cent of tricalcium phosphate. In southwestern Wyoming, in the Sublette Ridge, Beckwith Hills, and Cokeville areas, the phosphate is comparable in quality and thickness with the Idaho rock, though the thickness of

the high-grade bed, containing 70 per cent or more of tricalcium phosphate, is less uniform, apparently ranging from about 3 to 5 feet.

In the Wind River and Owl Creek mountains there are two phosphate beds, one of which is persistent throughout both ranges, and the other—the lower one—is limited to the southeastern part of the Wind River Range. On the northeastern slope of the Wind River Mountains, near Lander, along a front of 30 miles the upper bed is 3 to 5 feet thick and contains 40 per cent or more of tricalcium phosphate; elsewhere it is of only slight prospective value. In the same locality the lower bed across several townships is 2 to 4 feet thick and the content of tricalcium phosphate is 45 per cent or more.

The quantity of phosphate rock in the Wyoming fields is very great, though much of it is of medium or low grade. The Sublette Ridge, Beckwith Hills, and Cokeville areas are estimated to contain 37,200,000 tons of high-grade phosphate rock. It is not yet practicable to make estimates of the other fields. Rock has been shipped from Cokeville and Sage, Lincoln County.

At Cokeville, Wyo., tunnels have been driven at different levels on the strike of the bed which dips at a high angle. Overhead stopes have been opened through upraises from the drifts. The stopes are timbered and the ore settles between the timbers and is drawn through chutes into mine cars and dumped into the lower stopes. From the stopes above the lowest tunnel, the rock is dropped into cars and trammed out to bunkers from which wagons are loaded for hauling to the railroad. The rock is hard and air drills are used.

MONTANA.

Phosphate deposits occur at several places in Beaverhead, Granite, Powell, and Silver Bow counties, Mont. Phosphate was first discovered in Montana at Melrose in 1910 by a Government geologist, but the field in that vicinity has not been described in detail. The phosphate areas most fully known are at Elliston, Garrison, and Philipsburg.

In the Elliston area the main phosphate bed is 3 to 6 feet thick and carries 61 to 72 per cent of tricalcium phosphate. The outcrop is about 12 miles long and the field contains about 86,000,000 tons of high-grade rock.

In the Garrison field the economically important part of the phosphate deposit lies east of Hoover Creek. The trace of the bed is about 18 miles long and is in the form of a fishhook. The bed is believed to average 4 feet in thickness and analyses show that it contains an average of at least 60 per cent of tricalcium phosphate. If 3,000 feet is assumed as the depth of profitable mining, the Garrison field contains at least 97,000,000 tons of available rock phosphate. This estimate does not include layers of lower-grade rock in the eastern part of the field, or the thin bed of rock phosphate or sandstone containing nodules of phosphate in the western part of the field.

In the Philipsburg field the phosphate bed is so poorly exposed that few details of its thickness and character have been obtained. The evidence at hand, however, indicates that where it has not been deteriorated by faults or similar deformation the deposit is com-

parable in size and quality to that of the eastern part of the Garrison field.

Near Melrose a bed of phosphate 6 feet thick averages about 65 per cent of tricalcium phosphate. About 8 miles of outcrop is known, but excavations have not been made to determine the thickness of the bed throughout this distance. Sufficient data are not at hand to permit an estimate of the quantity. The outstanding withdrawals of phosphate land in Montana July 31, 1919, were 287,883 acres.

Phosphate rock mining in Montana has not yet begun, although some of the deposits are very favorably situated with relation to railroad.

FOREIGN PHOSPHATE DEPOSITS.

NORTH AMERICA.

Canada.—The principal phosphatic rock in Canada is apatite; it occurs in workable quantity in two main districts, one in the Province of Ontario, the other in the Province of Quebec. The district in Ontario is 100 miles long and 75 miles wide, extending from St. Lawrence River northward toward Ottawa River over Addington, Frontenac, Lanark, Leeds, and Renfrew counties; the district in Quebec occupies a belt 15 miles wide, extending northward from Ottawa for an unknown distance. These deposits, which have been worked mainly by quarrying, are now practically abandoned. Rock phosphate occurs in a thin bed near Banff, Alberta, but is not used.

SOUTH AMERICA.

Dutch West Indies.—In Aruba and Curaçao, islands off the coast of Venezuela, there are deposits of phosphate rock, which is mined in small quantity and shipped to Europe. It is reported that the output in 1914 was about 100,000 tons and averaged 85 to 90 per cent of calcium phosphate.

French Guiana.—Phosphate deposits occur on the island of Salut and on the Connetables, close to the coast of French Guiana. The rock is exported.

Peru.—In the region of Ocucajo in the department of Ica there is a deposit of nodular lime phosphate. It is not used because of a local preference for guano.

Chile.—A large and rich deposit of phosphate is reported to occur in the valley of Huasco River about 300 miles north of Valparaiso. It has not been developed.

EUROPE.

Belgium.—The phosphate-producing districts of Belgium are near Mons and Liege. The Mons deposit consists for the most part of low-grade phosphatic chalk containing less than 26 per cent of tricalcium phosphate. Near Liege phosphates occur as a layer half a meter thick of phosphatic nodules in a matrix of phosphatic sand and average 50 per cent of tricalcium phosphate. The higher-grade phosphate deposits are exhausted, but this material, of lower grade than is usually mined elsewhere, can be used economically for direct application to the soil because it occurs in centers of consumption. The production from 1910 to 1913 averaged more than

200,000 tons annually, making Belgium the leading European producer of phosphate rock.

France.—The principal deposits in France are in the Somme and Oise basins. The higher-grade deposits, carrying 50 to 80 per cent of bone phosphate, are nearly exhausted, and the principal production is phosphatic chalk carrying 25 to 27 per cent of bone phosphate. The output, which averaged more than 300,000 tons a year before the war, fell to 24,700 tons in 1916. There are low-grade deposits also in Cambresis, Ardennes, Auxerre, Burgundy, and in the Pyrenees Mountains.

Russia.—Important deposits of phosphate rock in Russia can be divided into the northern, central, and southern groups. The northern deposits are in the governments of Viatka, Vladimir, Kostroma, Riazan, Simbirsk, and Iaroslav; the central group is in the governments of Voronej, Kalouga, Koursk, Orel, Saratov, Smolensk, Tambov, and Chernigov; and the southern group in Podolia and Bessarabia, near the Galician frontier. The deposits of the southern group were the only ones exploited before the war, and the output was about 25,000 tons a year. This was very small in comparison with the size of the deposits, which are estimated to contain more than 1,500,000,000 tons. Some of the rock is high grade, carrying as high as 75 per cent of tricalcium phosphate, but the normal grade is about 50 per cent.

Spain.—The only deposits worked extensively in Spain are apatite veins at Aldea Moret, in the Province of Caceres. After being idle many years these deposits were reopened and produced 14,000 tons in 1916 and 28,000 tons in 1917.

Great Britain.—Low-grade phosphate in the form of beds of nodules occurs in Cambridgeshire, Suffolk, and Bedfordshire, England, and in Montgomeryshire, Wales. The production was 258,000 tons in 1876 but gradually decreased to less than 1,000 tons in 1900, since when all production has practically ceased, because the cheaply mined portions of the deposits have been exhausted. The total output from England since 1874 has been 1,205,000 tons.

Norway.—Apatite veins occur along the coast of southern Norway from Langesand to Lillesand, in the province of Kristiansand, and also in the Snarum district. The total production from 1851 to 1912 was 141,515 tons. Production reached 15,338 tons in 1882 but declined rapidly after 1891 and in recent years has averaged less than 1,000 tons annually.

AFRICA.

Tunis.—The principal deposits of phosphate rock in Tunis are the Gafsa fields in the southern half of the country. The phosphate occurs in beds several feet thick and only those carrying more than 58 per cent of phosphate are exploited. The deposits are of Eocene age, can be traced for several hundred miles, and constitute a reserve of hundreds of millions of tons. Tunis now produces more phosphate than any other foreign country, its annual output being between 1,500,000 and 2,000,000 tons, most of which goes to southern Europe.

Algeria.—The deposits of phosphate rock in Algeria are continuations of the deposits in Tunis. The two important mining districts are near the towns of Setif and Tebessa, in eastern Algeria. The

production is more than 300,000 tons a year, and the exported rock carries 58 to 68 per cent of lime phosphate.

Egypt.—Extensive deposits of phosphate occur in Egypt near the Red Sea in thin and irregular beds of the same geologic age (Eocene) as the deposits in Tunis and Algeria. The best deposits average 70 per cent of lime phosphate and the output in 1916 was 125,000 tons. There are mines 20 miles from Port Safalga and concessions 12 miles inland from Kosseir and also at Sebaia on the east bank of the Nile between Keneh and Assouan. Beds of phosphate are found in other districts on both sides of the Nile Valley. Practically all the raw rock phosphate produced is shipped from Egypt, principally to Japan, and contains 65 per cent or more of tricalcium phosphate.

Tripoli.—Deposits of phosphate occur 80 to 120 kilometers from the city of Tripoli in beds more than 1 meter thick. These beds probably are a continuation of the phosphate deposits in southern Tunis.

Morocco.—Deposits of phosphate are reported at El Boroudj, 125 kilometers south-southwest from Casa Blanca on the west coast and 70 kilometers from the end of a railroad. These deposits are said to be comparable to those in the Gafsa field in Tunis.

Senegal.—It is reported that at Dielor in Senegal, about the latitude of Cape Verde, which is the westernmost point on the African coast, there is a phosphate bed which is known to have a thickness of 2 meters to a depth of 64 meters. The rock carries only 50 per cent of tricalcium phosphate; hence it is not workable under present conditions, especially in view of the abundant high-grade rock in Algeria and Tunis.

Natal.—Phosphates have been found in Natal near Weenen, Ladysmith, and Byrnetown. The rock is in the form of reefs and nodules. The percentage of tricalcium phosphate in the phosphatic shales is too low for use in making superphosphates. The phosphatic nodules are of higher grade but too limited to be of value.

ASIA.

Siberia.—In the government of Uralsk, which is in southwestern Siberia bordering on the north end of Caspian Sea, there is reported to be 600,000,000 tons of phosphate rock. It is stated that the greater part of this material carries 17 to 20 per cent of phosphoric acid, which is equivalent to 36 to 43 per cent of tricalcium phosphate. The government of Turgai, which borders Uralsk on the east, is reported to contain 67,000,000 tons of phosphate rock, most of which carries 18 to 19 per cent of phosphoric acid, or about 40 per cent of tricalcium phosphate. The highest-grade material reported carries 24 per cent of phosphoric acid, equivalent to about 52 per cent of tricalcium phosphate. All the phosphate, therefore, is low grade. No production is reported from either of these localities.

Palestine.—Low-grade phosphate rock in sedimentary deposits of considerable extent and high-grade vein deposits along a fault line are reported as occurring between Es-Salt and Amman on the east side of Jordan. The sedimentary deposits occur also on the west side of Jordan. The known reserves are about 3,500,000 tons. The sedimentary deposits average about 48 per cent and the vein

deposits 77 per cent of tricalcium phosphate. As the vein material is suitable for export these deposits have been explored by a French company, but so far as learned there has been no output.

ISLANDS IN NORTH PACIFIC OCEAN.

Rasa Island.—The discovery of phosphate rock on Rasa Island, 500 miles east of Formosa, a number of years ago resulted in the formation of a Japanese company for the exploitation of the deposits. The rock is rich, carrying 75 per cent of phosphate of lime, and reserves are estimated at 2,800,000 tons. In 1915 Rasa Island yielded 50,000 tons.

Angaur Island.—A former German supply of phosphate is the deposit on Angaur Island, in the Pelew group, east of the southern end of the Philippines. Reserves on this island are estimated at 2,000,000 to 4,000,000 tons of phosphate rock, mostly high grade. Germany increased the output from 45,000 tons in 1910, to 90,000 tons in 1913. Japan has held this island since October, 1914, and is mining 30,000 tons or more of phosphate annually.

Other islands.—Deposits of phosphate consisting of replacements of dolomitic coral limestone by leachings from guano are reported on several other islands in Oceania, as Baker and Fanning islands in Polynesia, and Fais Island in the West Caroline Islands. It is probable that there are undiscovered commercial deposits on other islands.

ISLANDS IN INDIAN AND SOUTH PACIFIC OCEANS.

Australia.—North of Adelaide, South Australia, in the vicinity of Clinton, Kooringa, and Bright, there are pockety deposits of phosphate without regular stratification and of varying quality. Some is replacement of dolomitic limestone. An output of 4,000 to 6,000 tons is made annually. In the parish of Barrajin, County of Ashburnham, New South Wales, about 8 miles from Canowindra railway station, there is a small area in which phosphate occurs in irregular masses in residual clay resulting from weathering of limestone. The rock carries from 48 to 83 per cent of tricalcium phosphate.

New Zealand.—In the Otago district, at Millburn, near Clarendon, New Zealand, there are beds of phosphate 3 to 12 feet thick resting in pockets in limestone. There has been very little if any production.

New Caledonia.—On Huon Island, about 300 kilometers northwest of the north end of New Caledonia, there is a deposit of phosphate about 0.5 meter thick and carrying about 62 per cent of tricalcium phosphate. Production increased from 2,500 tons in 1910 to 8,400 tons in 1915. This is a French possession.

Christmas Island (Straits Settlements).—On Christmas Island, which lies in the Indian Ocean 190 miles south of Java, rock carrying 80 per cent of bone phosphate is quarried and shipped to Australia and Japan. The deposits seem to be irregular but are estimated to contain several million tons of very high-grade rock. The island belongs to the government of Singapore. Exploitation of the deposits by the British began in 1900. The exports in 1913 were 150,000 tons.

Ocean Island.—Phosphate rock of high grade is mined on Ocean Island, which is in Gilbert Archipelago, between the Marshall and Solomon Islands, east of New Guinea and north of New Zealand. On this and other coral islands in the equatorial belt which for ages have been rookeries of sea birds, leachings from the guano have impregnated the limestone, forming phosphate rock many feet deep. The deposits on this island, which are said to contain many millions of tons, are among the richest in the world. They have been operated since 1901, and have produced as much as 300,000 tons in a year. The output in 1916 was 70,000 tons of rock carrying about 85 per cent of tricalcium phosphate. This island is a British possession.

Pleasant Island.—Another British possession in the Gilbert Archipelago containing phosphate rock is Pleasant Island, which is also known as Nauru, Naru, or Ngaru Island. The deposits are similar to those on Ocean and Christmas Islands, being very high in calcium phosphate and low in iron and alumina. Germany formerly owned this island, but its interests were liquidated by the British in 1917.

Makatea Island.—Makatea, near Tahiti, in the Society Islands, is estimated to contain 10,000,000 tons of very high-grade phosphate rock irregularly distributed between reefs and pinnacles of dolomite. The deposits were developed so recently as 1910 and yielded more than 300,000 tons before 1917. Some of the rock carries 85 per cent of lime phosphate. The island is a French possession.

SURVEY PUBLICATIONS RELATING TO PHOSPHATES.

The following papers relating to phosphates have been published by the United States Geological Survey or by members of its staff.

The Government publications, except those to which a price is fixed, may be obtained free by applying to the Director, United States Geological Survey, Washington, D. C. The priced publications may be purchased from the Superintendent of Documents, Government Printing Office, Washington, D. C. Those indicated as "out of print" are not available for distribution. Geological Survey publications may be seen at the larger public libraries and the libraries of the larger educational institutions throughout the country.

GRAPHITE.

By Henry G. Ferguson.

INTRODUCTION.

Graphite occurs in nature in two forms, crystalline and amorphous, and each form has its own peculiar uses. The term crystalline or flake graphite is commonly understood to mean graphite in crystals large enough to be visible to the naked eye; much of the graphite called amorphous in the trade shows a crystalline structure under the microscope. Crystalline graphite occurs either in veins, as in the Ceylon deposits, or as flakes disseminated through the country rock, as in most of the deposits of crystalline graphite in the United States.

Amorphous graphite may occur wherever coal or other carbonaceous beds have been altered through the influence of neighboring bodies of igneous rock or of movements within the earth's crust. Crystalline graphite, both flakes and vein, is usually associated with granitic intrusives.

DOMESTIC PRODUCTION.

CRYSTALLINE GRAPHITE.

The sales of domestic crystalline graphite in 1918 were larger than ever before. The necessity for conserving shipping made it desirable that imports should be reduced as far as practicable, and the domestic industry responded well to the demand made upon it.

Domestic crystalline graphite sold in the United States, 1916–1918.

b 1916: California, Montana, New York, Texas; 1917: Alaska, California, Montana, Texas; 1918: California, Montana, Texas.

Total shipments of crystalline graphite in 1918, including both flake and dust, amounted to 12,861,839 pounds, valued at $1,454,799. As mine stocks were approximately the same at the beginning and

end of the year, this represents about the mine production. The sales show an increase of 22 per cent by weight and 33 per cent by value over those for 1917.

Estimates furnished by the producers of crystalline graphite show that out of the total sales of 12,861,839 pounds, 9,811,046 pounds, valued at $1,364,600, or 76 per cent by weight and 94 per cent by value of the total, was flake graphite for the most part suitable for crucible use. The remainder, 3,050,793 pounds, valued at $90,199, was dust or low-grade flake, probably averaging less than 50 per cent of graphitic carbon. The proportion of flake produced was higher than in previous years, owing in part to improved milling methods, whereby a larger proportion of the graphite was saved as flake, and in part to the fact that high freight rates and lack of demand made it unprofitable in many places to attempt to save the lower-grade graphite of the ore.

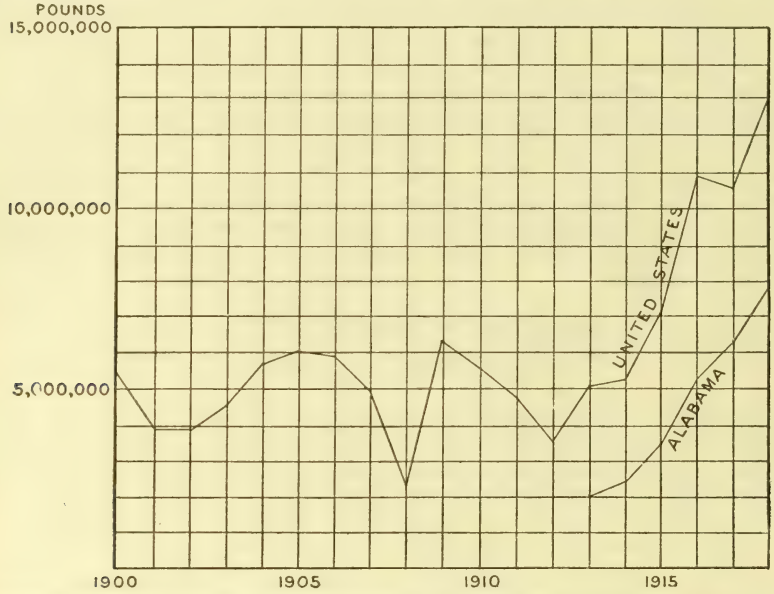

FIGURE 52.—Diagram showing production of crystalline graphite in the United States, 1900–1918, and in Alabama, 1912–1918.

As usual, the greater part of the domestic crystalline graphite was produced in Alabama, New York, and Pennsylvania. The product in these States was all of the variety known in the trade as flake graphite, which occurs as small flakes forming 3 to 10 per cent, by weight, of crystalline schists. In addition, crystalline graphite, resembling in a general way the Ceylon graphite, was produced in Montana, and a small quantity of flake graphite was mined in California and Texas. The number of mines reporting sales of crystalline graphite was 26 in Alabama, 1 in California, 1 in Montana, 3 in New York, 6 in Pennsylvania, and 2 in Texas.

In the first few months of 1918 the domestic industry was in a very difficult situation. The selective draft and the great increase of wages in other industries had caused an acute shortage of labor, particularly in Alabama, and the exceptionally severe winter had

also curtailed production greatly. Difficulty in obtaining fuel was also a serious factor in some places. The principal difficulty, however, was the freight embargo made necessary by the congestion of railroad traffic. The mines were able to make only small shipments under special license, and even those manufacturers who had been using domestic graphite were of necessity compelled to accumulate large stocks of imported material. Graphite was placed in classification "G" of commodities excepted from embargo on February 11, 1918,[1] and the situation improved somewhat, although the accumulated foreign stocks made the demand rather slack, and the continued shortage of labor increased the difficulty of production. Shipments of domestic flake during the first quarter of 1918 were less than 250 tons per month.

It soon became evident that the necessity for conserving shipping would require a restriction of imports. The War Trade Board, therefore, on March 23, 1918, prohibited imports of graphite by sea after April 15 until July 1 and authorized the importation of 5,000 long tons for the remainder of the year. These restrictions did not apply to graphite from Canada and Mexico. By a subsequent ruling nearly 1,000 long tons was licensed for import before July 1 and 1,200 tons for shipment from overseas ports during the last six months of the year. As it appeared that the stocks of imported graphite were sufficient to last the remainder of the year, a ruling was issued on July 2 prohibiting further imports during 1918. As dealers already had large stocks on hand the response of domestic production was gradual. Shipments of domestic flake for the second quarter of 1918, however, averaged over 300 short tons per month, and in July these shipments exceeded 600 short tons. The War Industries Board on August 10 requested all makers of crucibles to use 20 per cent domestic or Canadian flake in their crucible mixtures for the remainder of the year and 25 per cent during 1919, and stated that future applications for import licenses would be approved only for manufacturers complying with this request. On October 2 the War Trade Board issued a ruling permitting importations of graphite of crucible grade for manufacturers whose application had been approved by the War Industries Board. The requirement of 20 per cent of domestic flake immediately created a considerable demand for domestic flake and shipments from August to November averaged more than 500 short tons per month and would probably have been larger but for the epidemic of influenza. After the signing of the armistice the demand naturally fell off sharply, and domestic shipments were only about 240 tons per month during December, 1918, and January, 1919.

The War Trade Board on November 7 announced that the import restrictions were to continue in force until June 30, 1919, but on January 16, 1919, reversed this decision and removed all restrictions. The domestic producers, therefore, face competition from Madagascar and Ceylon, where large stocks have accumulated. At the same time the demand for graphite of crucible grade has fallen to a fraction of its war-time figure, and there seems no hope for any immediate increase in consumption for use in crucibles. The stock of flake graphite, exclusive of dust, on hand at the mines January 1, 1919, was approximately 1,000 short tons.

1918	6,560	69,455	6,431	1,454,799	12,991	1,524,254

AMORPHOUS GRAPHITE.

The sales of domestic amorphous graphite during 1918 amounted to 6,560 short tons, valued at $69,455, as compared with 8,301 tons valued at $73,481, in 1917, and 2,622 tons, valued at $20, 723, in 1916. The increased use of graphite in foundry facings has absorbed the increased output in this country as well as much imported amorphous graphite, chiefly from Mexico. The dust obtained as a by-product in the concentration of flake graphite and the artificial amorphous graphite produced in the electric furnace are competitors of the natural product. Sales of amorphous graphite were reported from four mines in 1918, as against six in 1917. The producing States were Colorado, Nevada, and Rhode Island. On account of the small number of producers, figures showing the production by States can not be published without disclosing individual returns.

MANUFACTURED AND SECONDARY GRAPHITE.

Graphite is manufactured chiefly by the Acheson Graphite Co., which utilizes electric power generated at Niagara Falls. The output has increased greatly in recent years and now forms an important element in the country's supply of graphite. The bulk graphite is made either from anthracite or from petroleum coke and is utilized mainly in lubricants but also for paints, foundry facings, boiler-scale preventives, and battery fillers. A high degree of purity is claimed for the lubricating graphite manufactured in this manner.

Artificial graphite may be used for any purpose to which natural graphite is put except in the manufacture of large crucibles. Recently, however, patents have been granted for methods of manufacturing crucibles in which artificial graphite may be employed. Under one method [1] a mixture of either natural, flake, Ceylon, or artificial graphite, fused bauxite (aloxite, alundum), and clay is used. The second method [2] is similar except that zirconia is used instead of fused bauxite.

Besides the graphite products in which artificial graphite enters into competition with natural graphite, there are a large number for which artificial graphite is particularly adapted. Chief among these are graphite electrodes, which are not made from natural graphite and the demand for which has greatly increased during recent years.

[1] U. S. patent 1289578, Dec. 31, 1918.

[2] U. S. patent 1289996, Dec. 31, 1918.

The figures given below represent only the manufactured graphite that comes into competition with natural graphite.

Graphite manufactured by the Acheson Graphite Co., 1915–1918.[1]

	Pounds.
1915	5,084,000
1916	8,397,281
1917	10,474,649
1918	9,182,272

Some work has recently been done on the commercial recovery of graphite from "kish." G. D. Dub, of the Bureau of Mines, recently visited a mill where "kish" graphite was being concentrated, and the following notes are quoted from his report.[2]

The product known as "kish" is a mixture of graphite, slag, iron oxide, fragments of iron, and other materials that accumulate about a pig-iron casting ladle or a Bessemer or open-hearth furnace. The graphite is formed during cooling by the crystallization of excess carbon from molten pig iron. The "kish" obtained for refining has contained 8 to 10 per cent of graphite carbon in the form of a light, thin, and fluffy flake.

The method of concentrating and refining "kish" is similar in many ways to the methods employed with natural graphite. The chief points of difference are that "kish" is not subjected to crushing, but is carefully screened and treated with magnetic separators.

"Kish" as a possible source of graphite should not be overlooked. At the present time, however, it is questionable whether enough of this material can be obtained to interfere or compete seriously with the mining of natural flake graphite.

Samples of the finished graphite received by the Geological Survey show a very clean, though light and thin flake, which should be excellent for lubrication.

A small quantity of high-grade graphite has been recovered from old crucibles by Harry Schmehl, of Chester Springs, Pa. The crucibles are crushed in a small mill and the graphite is recovered by oil flotation. Old graphite crucibles are also crushed and used in the manufacture of foundry facings but without separating the graphite from the matrix.

IMPORTS.

The following table shows the imports of graphite into this country since 1913. As the war has disarranged the usual trade routes and as the statistics of the Bureau of Foreign and Domestic Commerce necessarily show only the country from which shipments were made, it is necessary to draw some inferences as to the country of origin. Graphite entered in the import statistics as coming from France is probably all of Madagascar origin, and all graphite imported from Great Britain has been assigned to Ceylon, although it may include a small quantity of Madagascar graphite. Similarly, shipments from Japanese ports are assumed to represent Chosen graphite, as the production of graphite in Japan is small. The imports from Canada in 1914 and 1915 were in excess of the Canadian production for these years, so it is possible that these imports include reexported material.

Imports of doubtful origin are placed under "Other countries." Under this heading is included a small quantity from the Dutch East Indies, which is reported to have been crystalline graphite originating in Chosen.

1912	25,643	1,709,337	1918	19,498	3,092,475

EXPORTS.

Exports of graphite from the United States are comparatively small. In 1915 and 1916 there was a considerable increase in the exports of manufactured graphite articles and a marked decrease in the exports of unmanufactured graphite. During 1917, however, exports of unmanufactured graphite increased greatly and exports of graphite manufactures declined. Exports of both classes declined during 1918. The exports of pencils, which are not included in the classification of articles of manufactured graphite, has increased in recent years. Statistics of exports of pencils are given on page 235.

Graphite exported from the United States, 1912–1918.

Year.	Unmanufactured graphite.		Manufactures of graphite.
	Quantity (pounds).	Value.	
1912	4,640,802	$383,458	$177,082
1913	5,383,981	391,906	238,302
1914	3,920,693	277,386	215,878
1915	1,057,764	52,583	536,572
1916	1,595,608	98,118	1,339,259
1917	5,146,816	349,563	891,687
1918	1,907,719	121,555	731,518

Graphite crucibles, graphite, and articles manufactured therefrom were removed from the export conservation list on December 6, 1918.

PRICES.

Domestic flake graphite brought slightly lower prices for the best grades and rather higher prices for the lower grades in 1918 than in 1917; the average price on all crystalline graphite sold was higher owing to the greater proportion of high-grade material. The average prices received at the mines for all grades ranged from 10 to 17¾ cents a pound for No. 1 flake; from 7 to 13 cents a pound for Nos. 2 and 3; and from 1 to 1.8 cents a pound for dust. Flake graphite containing about 90 per cent of graphitic carbon sold for prices ranging from 15 to more than 18 cents a pound, and the graphite containing 85 per cent of graphitic carbon, which formed the bulk of the output, sold at 10 to 15½ cents—probably the greater part at 14 to 15 cents a pound. A small quantity of No. 1 flake with a content of graphitic carbon lower than 85 per cent brought prices ranging from 8 to 11 cents. During October some sales of Alabama graphite were made on a basis of 15½ cents a pound for material containing 85 per cent of graphitic carbon, with an allowance of 1 cent a pound for each per cent of graphitic carbon above that figure.

In general prices were lower during the early part of the year than in the summer and reached their maximum in September and October. Since the armistice there has been very little demand. Alabama graphite was quoted early in 1919 at 9 to 12 cents a pound, according to grade, but some sales have been made at higher figures.

The average prices received at the mines for No. 1 flake have been as follows: 1911 to 1914, 6 to 8 cents a pound; 1915, 7 to 10 cents; 1916, 10 to 16 cents; 1917, 12 to 18 cents; 1918, 10 to 17¾ cents.

Ceylon graphite of the better grades is more largely used by crucible makers than domestic flake graphite and commands a higher price. During the war the tremendous increase in manufacture of crucibles caused a demand for the Ceylon product much in excess of the available supply, and the price increased greatly over pre-war figures. The following table showing prices of Ceylon graphite c. i. f. New York for the years 1914–1918, is based on information furnished to the War Trade Board by importers.

Average prices of Ceylon graphite c. i. f. New York, 1914–1918.

[Cents per pound.]

Year.	Lump.		Chip.		Dust.		Remarks.
	First grade.	Second grade.	First grade.	Second grade.	First grade.	Second grade.	
1914	6½– 9½	7½– 8½	7¼– 7¾	6½– 7	4⅜– 5¼	3½– 4	Low, first half; high, second half.
1915	9⅝–20	8 –14	7–14	6½–12	7½– 9½	6½– 9½	Do
1916	20 –28	14 –21	13½–20	11½–17	9½–12	9½–10	Do.
1917	28 –32	21 –23	20 –23	17 –19	11 –13	10 –12	High level maintained throughout the year.
1918	28½–15¼	22 –14	21½–12½	18½–11	12 –10½	10 – 9	High, first half; low, second half.

It is believed that most of the purchases of Ceylon lump during 1918 were made at prices ranging from 21 to 24 cents a pound; chip, 15 to 20 cents a pound; and dust, 6 to 12 cents a pound. The customs figures give an average declared valuation of 13.3 cents a pound at the port of shipment for all Ceylon graphite imported in 1918.

In 1918 Madagascar graphite entered the market in quantity only during the first four months. Sales to consumers were made at 15 to 18 cents a pound for crucible flake. Had import licenses been freely granted, prices would hardly have exceeded 12 cents a pound. London prices for Madagascar graphite have been quoted in the Mining Journal (London) during 1918, and the following is a summary of these quotations:

January 5 to July 20, inclusive: 1,250 francs per ton f. o. b. Marseille for 80 per cent material and 900 francs per ton f. o. b. Tamatave for 85 per cent material, in each case with an allowance of 15 francs per unit of variation.

July 27 to November 30, inclusive: £50 per ton c. i. f. United Kingdom ports for 80 per cent material, with similar allowance for variation.

December 7 to 21, no quotations.

December 28: £46 per ton c. i. f. United Kingdom ports.

Prices for Canadian graphite averaged about the same as for similar grades of domestic graphite. Reports from consumers give 9 to 16⅔ cents a pound as prices paid for flake and three-fourths of a cent to 3¼ cents for dust. The customs figures give an average declared valuation of 3.8 cents a pound for graphite imported from Canada in 1918.

Domestic amorphous graphite brought widely varying prices, according to the grade of the material mined. Although the demand was generally good, the prices do not appear to have increased greatly during the year. The average price for sales at the mines was $10.59 a ton and the range in price was from $5 to $20 a ton. Most of the amorphous graphite on the market was of Mexican origin. This sold at widely varying prices according to the grade, from $35 to more than $100 a ton. Very little Chosen graphite was put on the market in 1918, owing to import restrictions. Some sales at $60 a ton were reported.

USES.

The following table shows the estimated proportion of graphite consumed in this country for different purposes. As compared with a similar table published some years ago [1] it shows relative increases in the graphite used for foundry facings and relative decreases in the graphite used for crucibles and stove polish. The percentage of graphite used for crucibles was probably considerably higher during the war. The writer desires to thank Mr. Charles E. Pettinos, 25 Church Street, New York, and Mr. Harry Dailey, of the Joseph Dixon Crucible Co., Jersey City, N. J., for assistance in the preparation of this estimate.

Estimated percentages (by quantity) of natural graphite consumed in the United States for various purposes.

	Per cent.
Crucibles	45
Foundry facings	25
Lubricants	10
Pencils and paints	5
Stove polish	5–10
All other uses	10– 5
	100

If artificial graphite were included, the percentages would be less for crucibles and greater for lubricants. If value rather than quantity is considered, about 70 per cent of the consumption should be credited to crucibles.

CRUCIBLES.

Graphite for making crucibles should be of the crystalline variety and should have a high degree of purity. Most makers of crucibles prefer to use Ceylon graphite either alone or mixed with varying proportions of American flake, usually not exceeding 25 per cent of the mixture. The reason for this preference is in part because the more nearly cubical fragments of Ceylon graphite have a much smaller surface area in proportion to their volume than the thin flakes of domestic graphite and hence require proportionately less clay as a binder. Ceylon graphite is also said to be more nearly free from undesirable impurities, such as mica and pyrite. It is possible, however, to use domestic flake graphite alone with good success in crucible manufacture.

Specifications as to graphite for use in crucibles vary widely. The standard for purity ranges from 85 to 90 per cent graphitic carbon and the lower limit of size from No. 12 silk bolting cloth (125-mesh) to No. 8 (86-mesh).

Dub [2] suggests the following specification for American graphite for use in crucibles:

> It is recommended that the graphitic carbon content of No. 1 flake be not less than 85 per cent. By graphitic carbon is tentatively meant the carbon remaining after the dried sample has been burned for three minutes at 800° C.

[1] Bastin, E. S.: U. S. Geol. Survey Mineral Resources, 1913, pt. 2, p. 188, 1914.
[2] Dub, George D., Preparation of crucible graphite; Bur. Mines War Min. Inv. Ser. 3, pp. 20–21, December, 1918.

The following tentative specifications as to screen analysis for No. 1 flake are recommended in cumulative percentages:

	Per cent.
Over 35 standard mesh	3
Over 65 standard mesh	50
Over 100 standard mesh	100

The following screen analyses of various types of No. 1 flake show the present practice in this regard:

Cumulative percentages of graphite for use in crucibles.

American No. 1 flake.[a]

	1	2	3	4	5	6	7	8
Over 20-mesh				0.1		0.1		
Over 35-mesh	0.1	2.5	3.3	15.4	5.7	6.7	9.7	8.2
Over 65-mesh	42.0	28.0	31.0	69.6	58.5	56.4	62.2	69.6
Over 100-mesh	94.8	60.0	74.3	95.6	93.0	97.0	92.4	99.7
Under 100-mesh	5.2	40.0	25.7	4.4	7.0	3.0	7.8	.3
Graphitic carbon	82.02	92.09	74.67		86.18	86.30		92.43

American No. 2 flake.[a]

	1	2	3
Over 20-mesh			
Over 35-mesh		0.2	0.1
Over 65-mesh		9.9	.3
Over 100-mesh	10.5	67.6	22.2
Under 100-mesh	89.5	32.4	77.8
Graphitic carbon	80.44	81.43	86.30

Canadian No. 1 flake.[b]

[Average of product from 7 mills.]

Over 20-mesh	1.76
Over 40-mesh	20.32
Over 60-mesh	87.32
Over 80-mesh	95.38
Over 100-mesh	96.48
Under 100-mesh	2.98

[a] Dub, G. D., op. cit., p. 20.
[b] Spence, H. S., Canadian graphite industry; Mines Branch Summary Rept. for 1917, p. 50, 1918.

It has been found in practice that although flake carrying 85 per cent of graphitic carbon can be readily produced, the cost of a product containing 90 per cent of graphitic carbon is very greatly increased. This is owing to the fact that small quantities of quartz, mica, and other impurities are interbedded in the graphite flakes themselves, and the flake must be broken to remove them. Seemingly pure graphite flakes were on analysis found to contain only slightly more than 90 per cent of carbon.[1] A sample of Ceylon graphite prepared for crucible use contained 85.06 per cent of graphitic carbon.[2] In purity, therefore, the American graphite compares favorably with that from Ceylon. The question of the relative value of American and Ceylon graphite for use in crucibles is now being investigated by the Bureau of Mines.

The graphite consumed for crucibles in this country during 1916 and 1917 amounted to about 24,000 tons each year, in large part for use in making munitions. It is probable that more than 90 per cent of the graphite used was of foreign origin. During 1918 the graphite consumed for crucibles was probably not more than 20,000 tons. This decrease was due in part to the increased use of electric steel

[1] Moses, F. G., Refining Alabama graphite for crucible use: Bur. Mines War Min. Inv. Series 8, p. 26, 1918.
[2] Dub, G. D., op. cit., p. 21.

furnaces and open-flame brass furnaces, in part to the export on war orders of raw materials rather than manufactured finished products, and in part also to the fact that a better quality of crucible was made, thus reducing the quantity of crucible graphite used. The normal peace-time requirements of crucible graphite, as measured by the apparent consumption for the years 1911 to 1913, probably do not exceed 13,000 tons a year. It is probable that the further demand for crucibles will diminish rather than increase. The following table shows the rapid increase in the manufacture of electric furnace steel, while the production of crucible steel has remained essentially stationary.

Steel ingots and castings produced in the United States, 1908–1917, by processes, in gross tons.[a]

	Crucible.	Electric.		Crucible.	Electric.
1908	63,631	.....	1913	121,226	30,180
1909	107,355	13,762	1914	89,869	24,009
1910	122,303	52,141	1915	113,782	69,412
1911	97,653	29,105	1916	129,692	168,918
1912	121,517	18,309	1917	126,716	304,543

[a] Am. Iron and Steel Inst.; Special statistical Bull. 4, 1918.

It is believed that with a return to normal conditions this difference will be further accentuated. Recent developments in the electric furnace as applied to nonferrous alloys also give promise of a decrease in the use of crucibles. It is even stated that the time is ripe for the practical elimination of the crucible from the brass industry.[1] A rocking electric furnace designed in the Bureau of Mines showed costs of operation about one-half that of the coke-fired crucible furnaces used in the same plant.[2] It was found that the cost to melt cupronickel, the most refractory alloy handled at the mint, in an electric furnace was less than half that in the gas-fired crucible furnace.[3]

The armistice found manufacturers and users of crucibles with large stocks on hand, and because of the decrease in use that has necessarily followed it will be some time before these are absorbed. The Bureau of the Census undertook a census of crucible stocks in the autumn of 1918, and an abstract of the returns is given below. It should be noted that figures for expected annual requirements refer to war requirements and that under present conditions the requirements will be much less.

[1] Gillett, H. W., and Rhoads, A. E., A rocking electric brass furnace: Jour. Ind. Eng. Chemistry, vol. 10, p. 459, June, 1918.
[2] Gillett, H. W., and Rhoads, A. E., Melting brass in a rocking electric furnace: Bur. Mines Bull. 171, 1918.
[3] Report of the Director of the Mint; abstract in Eng. and Min. Jour., vol. 107, p. 323, Feb. 23, 1919.

Stocks of finished graphite crucibles in the United States Oct. 1, 1918.

Owned by—	On hand and in transit.	In use.	Estimated annual requirements.
Manufacturers of crucibles	310,753	.....	.....
Users of crucibles for work in—			
Steel	72,552	8,626	678,094
Brass, bronze, and aluminum	178,470	14,658	1,058,958
Babbitt metal and solder	1,340	64	6,156
Miscellaneous	20,002	1,985	46,930
	583,117	25,333	1,790,138

It will be seen that even under war conditions the supply of crucibles of all sizes amounted to one-third of the estimated annual consumption. For the smaller sizes, up to No. 45, the total stocks were 111,886 and the estimated annual requirements only 83,841.

FOUNDRY FACINGS.

Next to crucibles, foundry facings probably consume more graphite than any other single use. For this use graphite is commonly mixed with talc or other substances in varying proportions. Amorphous graphite and the dust obtained as a by-product in the refining of flake graphite are used for the manufacture of foundry facings. Old graphite crucibles are also crushed and used for the same purpose. Usually a high degree of purity is not required. The advantages of graphite for this purpose are that it can be readily smoothed, to give a good surface to the mold, and that the combustion is regular but not too rapid, so that the film of gas formed prevents any adhesion of the metal to the sand of the mold, but is not sufficient to cause irregularities in the casting. A rough estimate of the graphite used in the country for foundry facings places the quantity at 10,000 tons a year.

LUBRICANTS.

Graphite for lubrication appears to be in constantly increasing demand. For this purpose freedom from abrasive impurities is the prime consideration. Flake graphite, amorphous graphite, and artificial graphite are all used for lubrication. The graphite may be used either alone or combined with greases and oil, or, as with colloidal graphite, in suspension in oil (oildag) or water (aquadag). Graphitized metals formed by impregnating copper or babbit with graphite are used for bearings and sliding contacts.

The use of graphite in lubrication greatly reduces the cost of operating machinery of any kind and increases efficiency. It is stated that the increased use of colloidal graphite during the war enabled Germany to effect a saving of at least 15 per cent in the quantity of lubricating oil required.[1]

It is difficult to form any close estimate of the quantity of graphite used in this country for lubrication. Probably the annual consumption is less than 3,000 tons of natural graphite, exclusive of artificial graphite.

[1] Chimie et industrie, vol. 1, p. 168, 1918.

PENCILS.

The use of graphite in "lead" pencils is the most familiar as well as the most ancient use. In the sixteenth century pencils were made in England from the graphite of the famous Borrowdale mine. The graphite was at first cut into strips, and it was not until late in the eighteenth century that the present method of making the "lead" in pencils from a mixture of graphite and clay was adopted. Graphite for making pencils must be free from impurities and finely divided in order to make an even mixture with the clay. Formerly Bohemian graphite was largely used for this purpose, but this has now been superseded by Mexican amorphous graphite.

Prior to the war pencils were imported in large quantities, principally from Germany and Austria. The imports of foreign pencils are now insignificant, and large quantities of pencils of American manufacture are exported to all parts of the world.

Value of pencils and pencil leads exported from the United States, 1918.[a]

[Figures compiled by the Bureau of Foreign and Domestic Commerce.]

Country.	Value.	Country.	Value.
France	$32,326	China	$17,905
Italy	77,240	British India	65,088
Spain	179,706	Straits Settlements	10,148
England	542,720	Dutch East Indies	33,037
Canada	425,927	Japan	50,740
Mexico	104,154	Australia	155,157
Cuba	127,177	New Zealand	20,134
Argentina	166,069	Philippine Islands	96,525
Brazil	110,741	British South Africa	76,901
Chile	58,198	Other countries	85,816
Colombia	12,807		
Peru	26,806		2,497,208
Uruguay	21,886		

[a] Commerce Repts., Apr. 12, 1919, p. 301.

Although the manufacture of pencils is an important industry the quantity of graphite used in it is comparatively small, and the manufacture of pencils in this country does not consume much more than 1,000 tons of graphite a year.

OTHER USES.

Graphite has a wide variety of uses other than those enumerated above. It is used extensively in paints for iron roofs and other iron surfaces and makes a coating that has great permanency. The graphite is commonly mixed with silica. Graphite is used for fillers of dry cells, electrotyper's leads, motor brushes, pipe cement, stove and metal polish, for glazing powder, polishing shot, minimizing water friction on yacht and launch bottoms, and for other purposes. Graphite added to impure boiler water loosens old scale and prevents the formation of scale.

REVIEW BY STATES.

ALABAMA.

As usual, Alabama led in the production of crystalline graphite. The sales for 1918 amounted to 7,795,475 pounds, valued at $999,152, an increase of 25 per cent in quantity and 39 per cent in value over 1917. Sales of flake greatly exceeded those for 1917, but there was little market for dust and many operators made no attempt to save it.

The year 1918 was marked by improvement in milling methods which have to some extent compensated for the tremendous increase in costs. Alabama milling practice has been described in detail in a recent publication of the Bureau of Mines.[1] At present the average recovery from the Alabama ores, which contain about 2½ per cent of graphite, is about 19 pounds of No. 1 flake, 5 pounds of No. 2 flake, and 3 pounds of dust per ton of ore.

The following companies either reported sales or stated that they had begun the production of graphite in 1918:

Alabama graphite companies.

Company.	Office.	Mine.
Alabama Graphite Co	Ashland	Ashland.
C. B. Allen Graphite Co	do	Do.
American Graphite Co	do	Do.

The Quenelda Graphite Corporation has recently absorbed the following graphite plants in the Alabama field: The Quenelda Graphite Co., American Graphite Co., Crucible Flake Graphite Co., Carbon Mountain Graphite Co., Peerless Flake Graphite Co.

NEW YORK.

The sales of graphite in New York in 1918 amounted to 3,266,518 pounds, valued at $273,188, an increase of 11 per cent in quantity and 4.5 per cent in value over the output in 1917. The ore of the New

[1] Dub, G. D., Preparation of crucible graphite: Bur. Mines War Min. Inv. Ser. 3, pp. 3–12, December, 1918.

York deposits averages 4 to 6 per cent of graphite, but is harder and more siliceous than the lower-grade Alabama ore.

The following companies in New York reported sales in 1918:

Graphite Products Corporation, Saratoga Springs.
American Graphite Co. (Joseph Dixon Crucible Co., owner), Graphite.
Hooper Bros., Dresden.

The graphite deposits of New York, including prospects and abandoned mines as well as those in active operation at the present time, are described in great detail in a recent report by H. L. Alling.[1] Many microscopic and chemical analyses of the ores are given. Alling divides the deposits into those of the northern area, where most of them are of the limestone and contact type, and those of the southern area, where they are characteristically in the bedded form. The northern area includes the deposits of Essex County and a group of prospects and abandoned mines in Ticonderoga Township. None of the mines in this area are now in operation. In most of these deposits graphite has developed in sedimentary rocks, chiefly limestone, in contact with pegmatite and other igneous rocks. These are too uncertain, too pockety, and too small in extent to be minable under present conditions.

The graphite schists of the southern area at present furnish the commercial deposits of the Adirondacks. These are divided into four groups, as follows:

1. The normal quartz schist, carrying 5 to 7 per cent of graphite. This is the ore mined at present. It exists as two beds in some properties, as one bed in others. It ranges in thickness from 3 to 30 feet. The upper and the lower layers tend to be micaceous, and, as a general rule, the mica content increases with increase in the feldspar content.

2. A feldspar-quartz schist, carrying 6 per cent of graphite and 10 per cent of micaceous minerals.

3. A phase of the quartz schist affected by contact metamorphism, with the development of pyroxene and tourmaline. The graphite has been redistributed, and certain layers show an abnormally high content.

4. A meta-arkose or "arkosite" which consists almost entirely of potash feldspar. Alling's mineral analysis shows 1.6 per cent of graphite in ore of this type.

Present milling practice makes only the material of the first group available as graphite ore. Alling estimates that the properties of Faxon, Hooper Bros., the Flake Graphite Co., and the Graphite Products Corporation have a combined reserve of 10,000,000 to 13,000,000 tons of graphite schist, half of which is readily available. A reserve of 5,000,000 tons of available ore, carrying 3 per cent of recoverable graphite, would yield 300,000,000 pounds of graphite, enough to maintain the present rate of production from this State for nearly a century.

The schist ores are considered to be of organic origin, the change from organic carbon to graphite having been effected by the heat and pressure accompanying mountain building stresses. The contact and vein types are considered to be of inorganic origin, in that the graph-

[1] Alling, H. L., The Adirondack graphite deposits: New York State Mus. Bull. 199, Albany, 1918.

ite was formed from the breaking up of gaseous oxides of carbon in the pegmatites.

Alling's paper also describes the milling methods in New York. Present milling practice, however, is described in more detail by Dub.[1]

PENNSYLVANIA.

Sales of graphite in Pennsylvania during 1918 amounted to 1,016,900 pounds,[2] valued at $112,059, an increase of 26 per cent in quantity and 45 per cent in value over the output in 1917.

The following operators in Pennsylvania reported sales of graphite during 1918:

T. D. Just Co., Chester Springs.
W. E. Pomeroy, Byers.
E. E. Hargrave, Byers.
Harry A. Schmehl, Chester Springs.
Standard Carbon Co., Pikeland.
Rock Crucible Graphite Co., Chester Springs.

The producing graphite deposits of Pennsylvania are in the vicinity of Byers and Chester Springs, in Chester County. The material chiefly mined is a graphitic schist, rich in lime-silicate minerals. In several mines this rock is deeply weathered, and the soft clayey material can be mined cheaply. Everywhere intrusions of pegmatitic granite are noticeable. The pegmatite is for the most part in thin sills parallel to the schistosity and is barren of graphite except to a small extent near the contact. The mine of the T. D. Just Co. is on the top of the hill about a mile south of the village of Chester Springs. The ore is exposed in a 30-foot open cut and consists of soft weathered material throughout. Considerable pegmatite is present, but for the most part in narrow bands only. The ore is dug by a steam shovel and hauled to the mill a short distance away. The oscillator system [3] is used for concentration.

Across Pine Creek to the northeast a continuation of the same band of graphitic schist has been mined in former years. The mine of the Federal Carbon Co. is about half a mile northeast of these workings and a mile east of Chester Springs. Graphite was formerly mined in open cuts, but the present company is doing underground work. The mine is developed by a shaft 120 feet deep, with drifts about 200 and 100 feet long at the 80-foot level. Even at this depth the ore is weathered.

The quarry of the Rock Crucible Graphite Co. is on the top of a hill about a mile northwest of Chester Springs. In contrast to the material mined farther east, the ore is hard and requires drilling. The workable portion consists of hard schist about 12 feet thick, which dips 30° E. and grades into micaceous material above. Much pegmatite in thin seams parallel to the schistosity is present. The ore is trammed through a tunnel to the mill a quarter of a mile to the north. The electrostatic process is used for concentration.

The Graphite Products Co. is operating a large quarry just south of Byers. Formerly the deposit was mined underground, and the old drifts are still to be seen in the quarry face. The ore, though of unusually high grade in places and weathered throughout, is very

[1] Dub, G. D., op. cit., pp. 12–14.
[2] Includes an estimate for the Graphite Products Corporation, which refused to furnish information.
[3] Dub, G. D., op. cit.

uneven in tenor, and the best material occurs in thin bands. The largest flakes are in a greenish clayey material, usually close to the pegmatites. About half the face appears to be of pegmatitic material. The mill uses log washers with burr mills for finishing.

The old Tonkin mine, southeast of Byers, has been leased by E. C. Hargrave. The workings consist of a large quarry and of smaller prospects in other parts of the property. Much of the ore is of high grade, and all of it is sufficiently weathered to facilitate mining, but the individual seams of good material do not exceed 10 feet in thickness. Some very large flakes, as much as half an inch in diameter, occur in places. The mill uses oscillators, similar to those at the Just mill, for concentration. The finishing plant consists of screens, rolls, and burr mills for final grinding.

Besides the mining operations in this district, there are two other plants which deserve mention. Frederick B. Chester has a mill near Chester Springs, where the dust from the flake graphite mills, averaging 30 or 40 per cent of graphitic carbon, is refined by a special process to a high-grade product suitable for battery fillers and high-grade lubricants. At Pikeland, Harry Schmehl has a small mill where ore from neighboring mines is treated and graphite is also recovered from old crucibles.

TEXAS.

The following notes on graphite operations in Texas are quoted from the report by Dub already cited:[1]

Three properties are now operating in the State. The Southwestern Graphite Co., 9 miles west of Burnet, and the Burnet-Texas Graphite Co., 7 miles west of Burnet, have developed open pits; the Dixie Graphite Co., 4 miles northeast of Llano, is mining underground.

At the property of the Southwestern Graphite Co., the overburden, which varies in thickness from 2 to 8 feet, is a hard-baked detritus containing large boulders of ore. It contains considerable clay and vegetable fiber and is said to average 3 or 4 per cent graphitic carbon, only a small part of which can be recovered as No. 1 flake stock. Accordingly, this material is now being loosened by means of a plow, aided by a snatch block, and is being disposed of as waste. In loosening overburden of this character, black powder might advantageously be used.

The ore body at present is being crosscut, preliminary to the development of two working faces along the strike of the ore, which is 80 to 100 feet thick and dips about 65° SE. It can be followed on this company's property with a slight interruption for almost three-fourths of a mile along the strike.

In mining, a Keystone wood-fired churn drill is used for drilling holes 5½ inches in diameter. These are placed at the corners of 12-foot squares, the first row of which is 12 feet from the last crack of the previous blast. All holes are drilled to a depth of 25 or 30 feet, which is 5 feet below the elevation of the bottom of the open pit. Blasting gelatin of 60 per cent strength is used for breaking. An Erie wood-fired steam shovel, with a dipper capacity of five-eighths of a cubic yard, loads the broken ore into 5-ton side-dump contractors' cars, which are hauled to the mill by a Whitcomb gasoline locomotive. Large boulders are placed to one side by the shovel and block-holed with self-rotating hammer drills of the "jackhammer" type.

The Burnet-Texas Co., 2 miles northeast of the Southwestern Graphite Co., is operating in a small way on the same graphite schist series. Here, however, the ore contains more frequent granite and pegmatite intrusions, and as now developed appears to contain less graphite that would make No. 1 flake stock. Besides an open pit, this property is now being prospected by a vertical shaft.

The Dixie Graphite Co., 4 miles northeast of Llano, obtains its ore from underground mining. The deposit dips to the southeast at a flatter angle than at the Southwestern Graphite Co.'s property. The ore near the surface contains considerable quantities of amorphous graphite and fine flake. The ore at present mined underground is a

[1] Dub, G. D., op. cit., pp. 16–17.

better grade as regards the size of flake and contains considerably more pyrite and mica than were obtained in the surface ore. On this property in the past much development work was done with a view to mining gold and molybdenite ores, but these efforts were not successful.

Two plants use the oil-froth flotation methods; at a third plant Huff electrostatic machines have been installed. These plants do not differ materially from mills previously described, except that in each a rough concentrate analyzing 70 to 80 per cent of graphitic carbon and remaining on an 80 or a 90 mesh screen is recovered.

No refining plants are as yet in operation.

* * * * * * *

The Texas district is fortunate in being able to obtain a fair supply of native white labor, which has not been drawn from the district by the attraction of high wages paid in our various manufacturing centers. This labor, of course, is inexperienced in mining but in these times of stress furnishes a more efficient potential supply than is present in the Alabama field.

OTHER STATES.

The California Graphite Co., of Los Angeles, continued its production of flake graphite during 1918. This deposit has been described in detail in a previous report.[1]

The Crystal Graphite Co., of Dillon, Mont., continued its production of high-grade vein graphite of a type similar to the Ceylon product. Deposits of flake graphite in Montana were prospected in 1918, but no production is reported, and it is doubtful whether present market conditions justify the development of flake deposits at so great a distance from the market.

A small quantity of crystalline graphite was mined near Shelby, N. C., by the General Graphite Co., of Birmingham, Ala. The first shipment of graphite was made in January, 1919. This company also reported development work on South Carolina deposits. Specimens of flake graphite have been received from Hickory, N. C.

Samples of good-grade flake have been received from Goochland, Va., where E. M. Gathright is developing a graphite property.

A company was organized to reopen the abandoned graphite deposit at Highbridge, N. J., but did not begin operations.

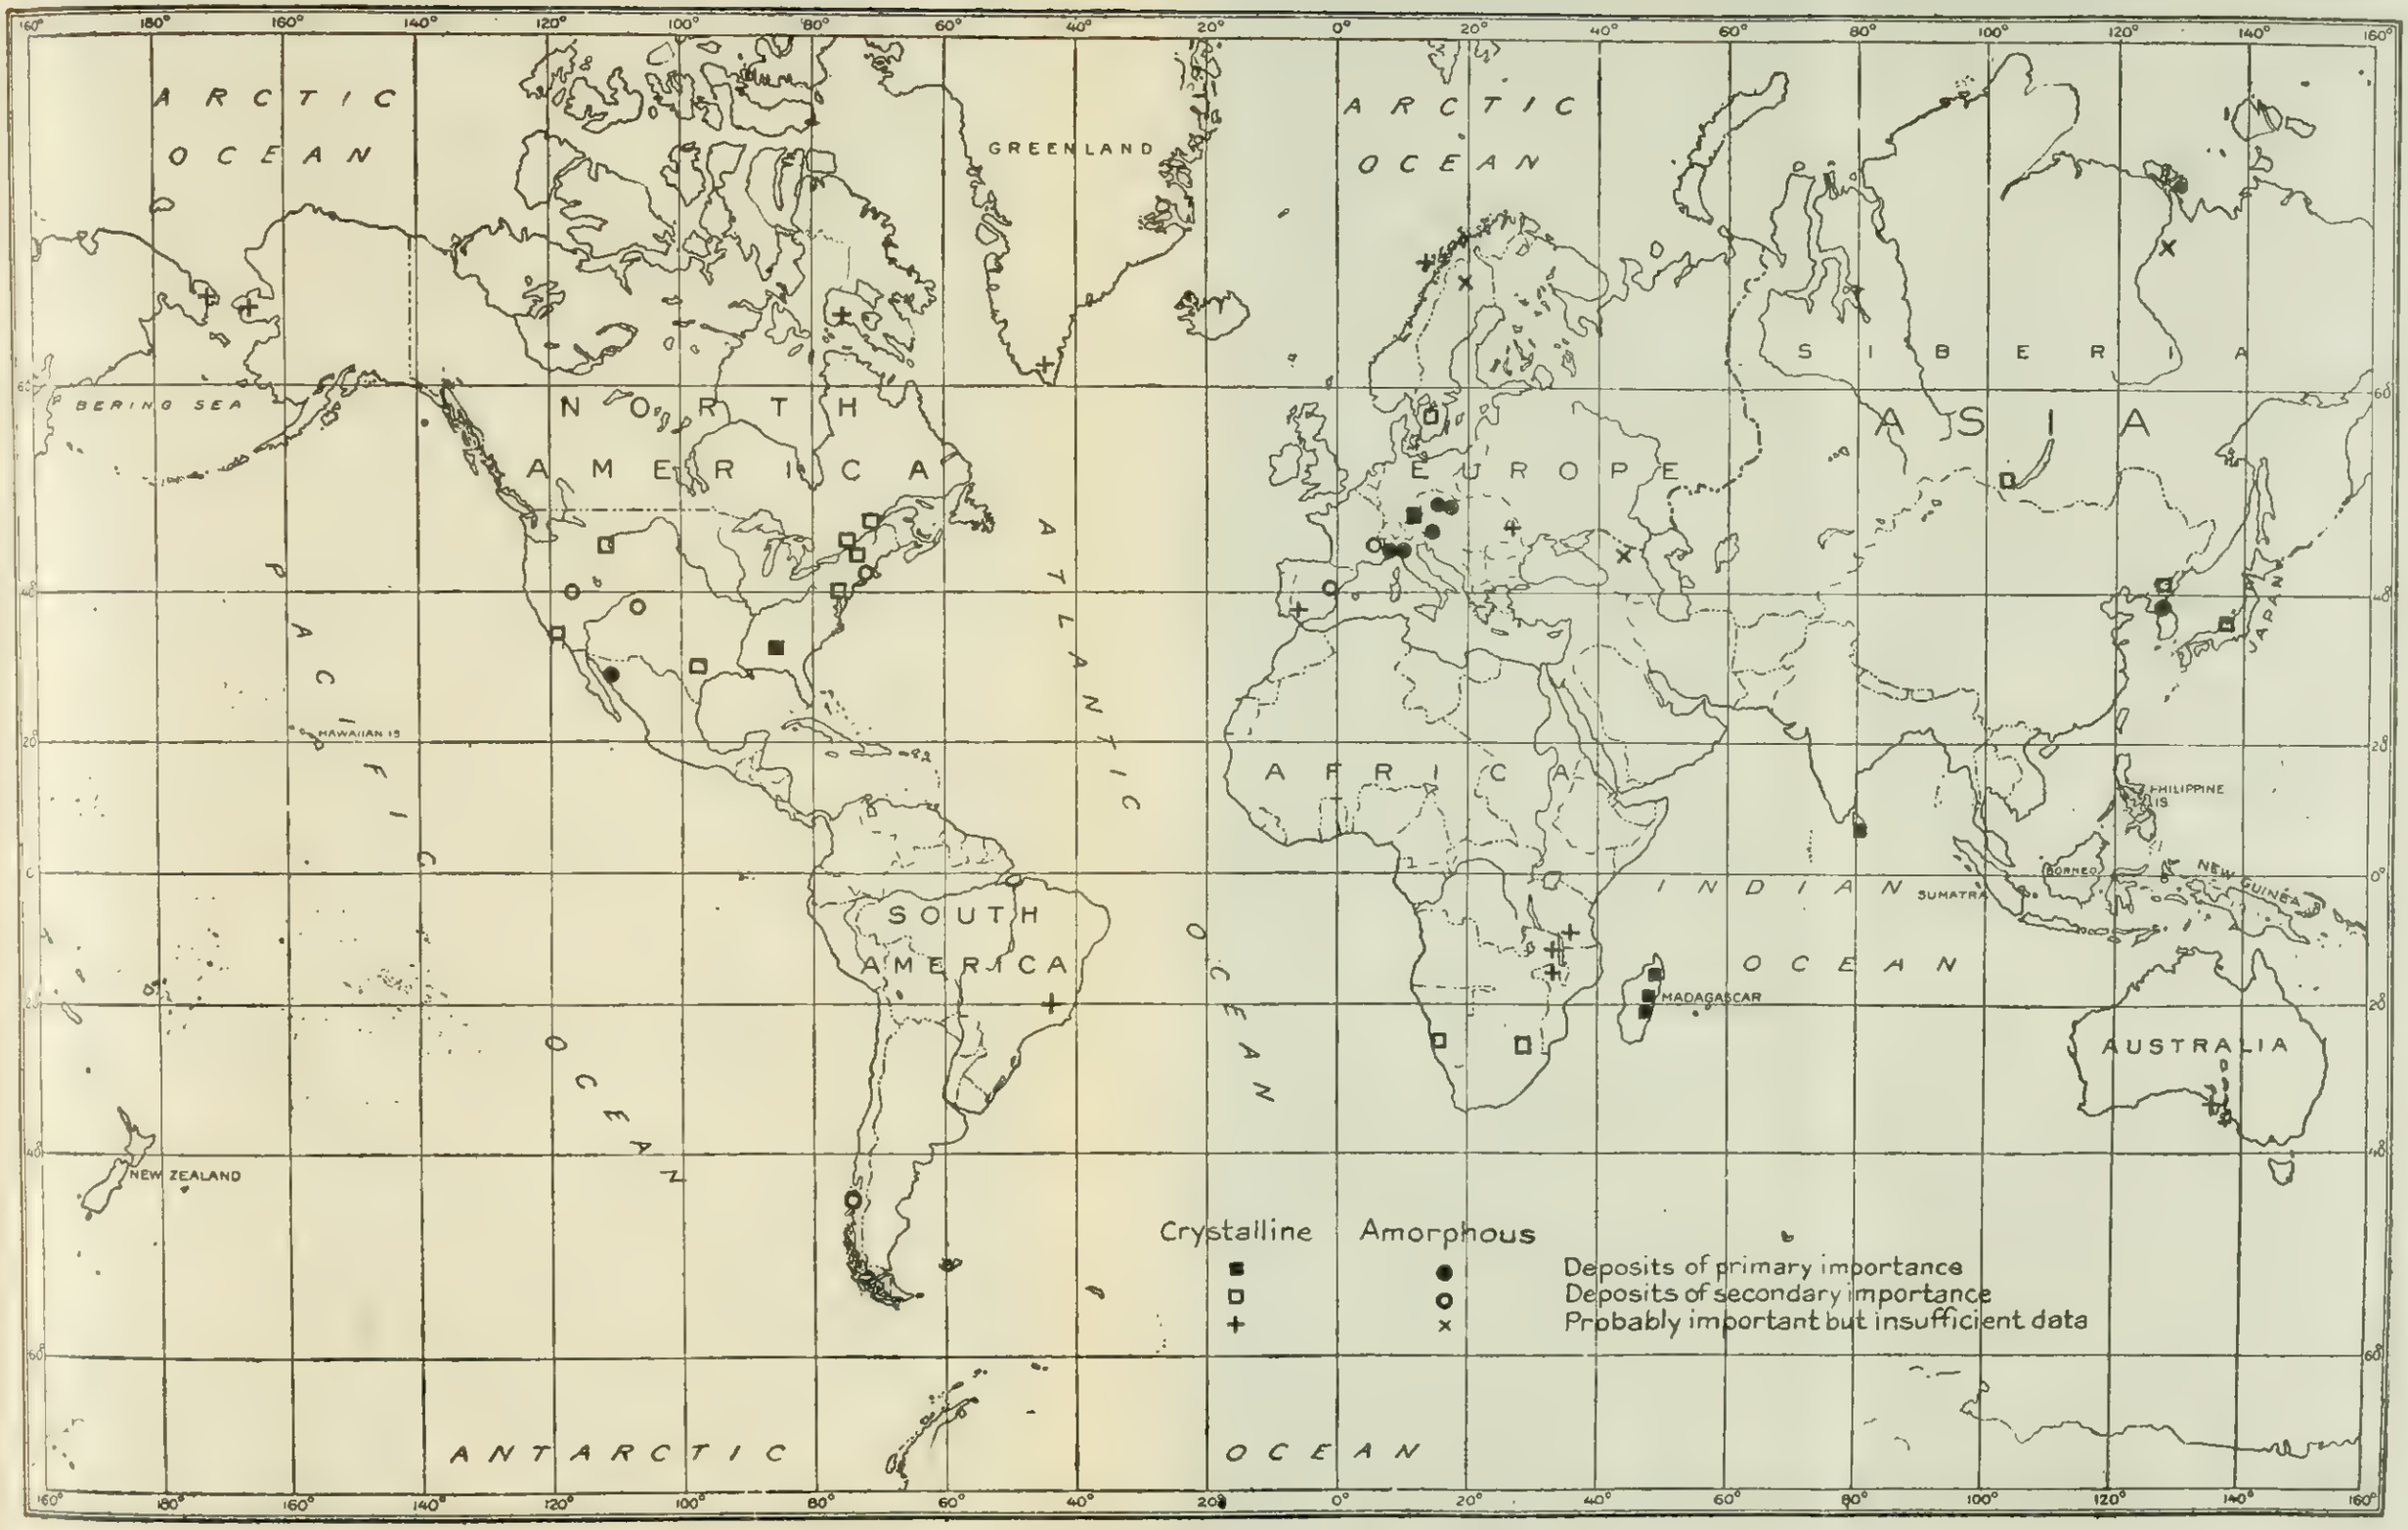
Rhode Island furnished a large production of amorphous graphite in 1918 from mines near Providence. The graphite has resulted from the metamorphism of coal beds, and is largely used for foundry facings. The operators reporting production were the Graphite Mines Corporation, of New York, and Frank D. Fenner, of Providence. Amorphous graphite was also produced in Colorado by Woodruff & Woodruff, of Greeley, from a deposit in the Quartz Creek district, and in Nevada by the Carson Black Lead Co., of Carson.

FOREIGN DEPOSITS.

WORLD'S PRODUCTION.

The following table shows the world's production of graphite by countries since 1914, so far as statistics are available. Tables of production for 1913 and earlier years have been published in the reports on graphite for 1906 to 1917, inclusive. The production of the leading graphite-producing countries from 1902 to 1918 is shown graphically in figure 53, and the location of the principal graphite deposits of the world is shown in Plate II.

[1] Bastin, E. S., Graphite in 1915: U. S. Geol. Survey Mineral Resources, 1915, pt. 2, pp. 88–89, 1916.



MAP SHOWING LOCATION OF THE PRINCIPAL GRAPHITE DEPOSITS OF THE WORLD.

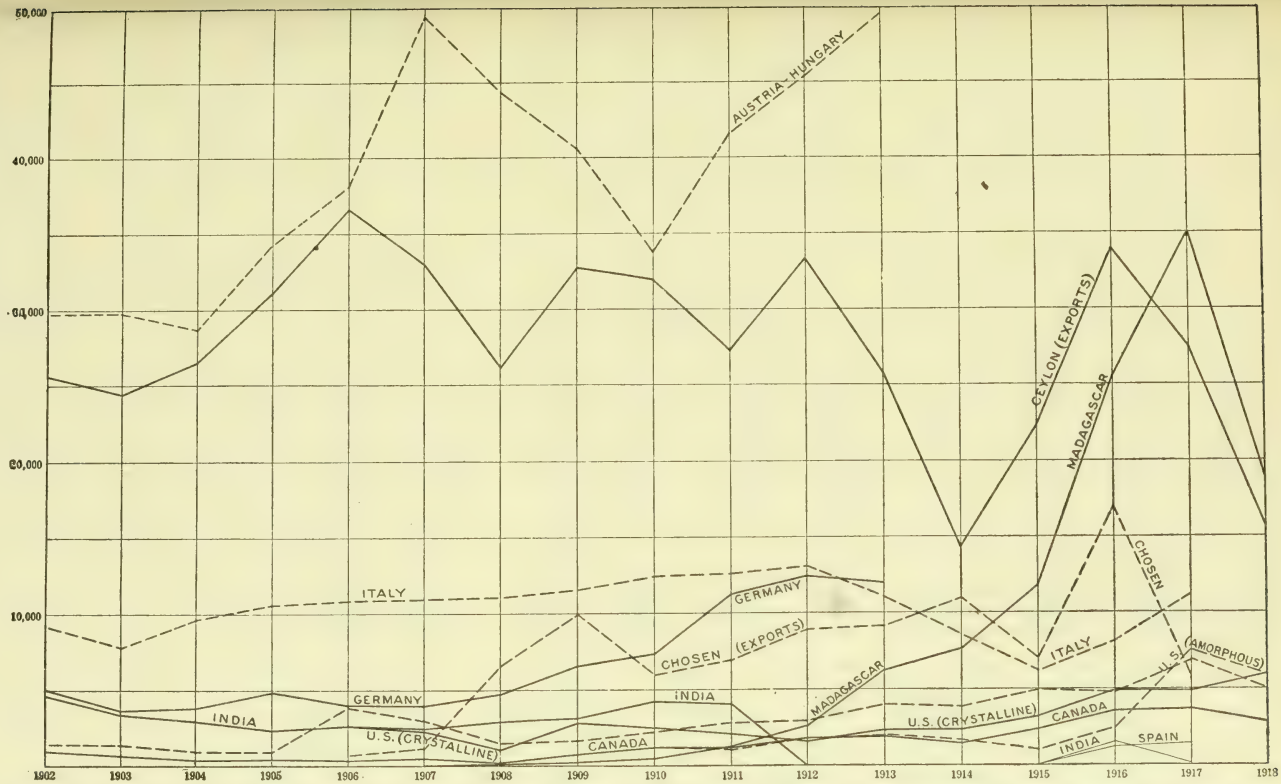


FIGURE 53.—Diagram showing production of graphite in principal countries in 1902–1918. Full lines indicate principally crystalline graphite; dotted lines, principally amorphous graphite. Production of amorphous graphite in the United States prior to 1908 is not included. Figures for production of Chosen from 1909–1912 are estimates based on value of exports.

NORTH AMERICA.

CANADA.

The Canadian output was slightly smaller in 1918 than in 1917. The greater part of the output comes from the Province of Ontario, where the Black Donald mine, at Calabogie, is the principal producer. This graphite is used largely for foundry facings in the United States. Canadian flake is also used by manufacturers of crucibles, and some of them prefer it to the Alabama flake. The flake graphite occurs in crystalline limestone in Haliburton and Hastings counties, Ontario, where the graphite content ranges from 10 to 15 per cent, and in more or less calcareous bands intercalated with gneiss in the Buckingham district, where the tenor is 7 to 10 per cent.[1] A small output of lump graphite, similar to Ceylon lump, has been obtained from Baffin Island.

The graphite deposit of the Globe mine, in the Port Elmsley district, Ontario, has been recently described by Wilson.[2] Here the graphite is largely concentrated on the crest of an anticline of silicified limestone intruded by pegmatite dikes.

The completely silicified portions of the limestone are richer in graphite, and Wilson considers it probable that the source of the graphite is the carbon content of the original calcium carbonate which formed the limestone.

Most of the Canadian graphite is exported to the United States, but crucibles, foundry facings, and pencils are also manufactured in Canada. Besides natural graphite there is also a production of artificial graphite in Canada, which amounted to 263 short tons in 1916 and to 548 tons in 1917.[3]

MEXICO.

Owing to the exclusion of Chosen graphite by embargo restrictions, Mexican graphite during the greater part of the year was the only high-grade foreign amorphous graphite on the American market. The figures for the Mexican production given in the foregoing table are those for imports into the United States, but they represent the production fairly accurately, as the mines are operated by American companies and the product is refined in this country. Mexican production was low in 1915, owing to the disturbed political condition of the country, but increased in 1916 and 1917.

The decrease in 1918 was due in part to the epidemic of influenza which ravaged northern Mexico in the later part of the year.

The following notes on the Mexican deposits are quoted from the Survey report on graphite for 1913:[4]

For a number of years the United States Graphite Co. has been an important producer of amorphous graphite from mines in the State of Sonora, Mexico. The crude material is shipped by rail to Saginaw, Mich., where it is ground in continuous feed tube mills and is subsequently air floated. Some of the product is mixed with

greases to make a prepared lubricant or with other pigments and oil for black, dark-green, and dark-brown paints. The remainder is marketed in the dry state for practically all the purposes to which any graphite is applied, except the manufacture of crucibles and related refractory products.

The following description of the graphite mines of Sonora, Mexico, has been furnished by Frank L. Hess, of this Survey, who visited these properties early in 1909:

"The Santa Maria graphite mines, which are owned by the United States Graphite Co., of Saginaw, Mich., are situated about 20 miles south and a little east of La Colorada, in central Sonora. They are the largest amorphous-graphite mines in the western hemisphere and probably in the world. The country rock is composed of metamorphosed sandstone, ranging in fineness from shaly material to conglomerate containing pebbles of 1½ inches diameter. Considerable andalusite in small crystals is developed in the sandstone. The rocks are probably of Upper Triassic age. They are intruded by granite, which has been the metamorphosing agent. Intercalated with the sandstone are at least seven beds of graphite, ranging in thickness up to 24 feet and standing at high angles. The rocks are considerably folded, and the graphite beds show the effect of movement more than the inclosing sandstone; in places they are almost cut off through squeezing, while in other places they show thickening. The graphite beds are also intruded by granite dikes, and in places the walls are of granite. The graphite was undoubtedly formed through the metamorphism of coal beds, which in other parts of the State are to be found in the form of coke, anthracite, and bituminous coal. The graphite of the Santa Maria deposits is entirely amorphous, and from the main vein worked averages about 86 per cent graphitic carbon. Specimens may be picked which carry 95 per cent graphitic carbon. The graphite is shipped to Saginaw, Mich., for refining. A large part of the best pencils, both of European and American manufacture, are made from this graphite. It is also used as a lubricant, for powder coating, and for foundry facings. A few miles north of Torres, and 3 miles west of the railroad, Pettinos Brothers, of Bethlehem, Pa., own graphite deposits, for which a good price was paid a few years ago. A small amount of graphite was shipped, but the property is now lying idle. Prospecting is being carried on for graphite on the east side of Yaqui River, a few miles above Onavas. The geology is similar to that of the deposits at Santa Maria, about 75 miles west. At San Marcial, between Santa Maria and Onavas, coal is found partly graphitized; and at points on Yaqui River above Onavas unaltered coal beds are reported, which, it is said, the Southern Pacific controls and will use for fuel on its Mexican lines."

SOUTH AMERICA.

BRAZIL.

A little crystalline graphite has been imported into this country from Brazil, but no data are available as to the production. Graphite is reported to be found in considerable quantities in the State of Sao Paulo [1] but has not yet become commercially important. Graphitic schists containing 10 to 11 per cent of carbon are mined in the State of Rio, and the material is used locally for the manufacture of pencils.[2] Graphite appears to be abundant in Minas Geraes, particularly in the Lafayette district, where it occurs in graphitic schists and also in veins ranging in width from a few millimeters to about a meter.[3] These deposits do not appear to have been worked.

A number of deposits have been located in different parts of the State of Bahia but have never been developed. Deposits of flake graphite are known at Cachoeira, Castro Alves, and Jaquitionha River, and amorphous graphite is found at Nazareth, Camisao, Santa Luzia, and Areia.[4] At Nazareth the graphite occurs in connection with manganese deposits.[5] Veins of graphite 19 to 40 inches thick containing masses weighing hundreds of pounds are

reported to occur at Emparedado, in Bahia, but lack of transportation has prevented development.[1]

URUGUAY.

Graphite has been mined near Isla Mala, in the department of Florida, Uruguay, and deposits are known in other parts of the country.[2] The graphite is said to be of poor grade, and there are no mines at present in operation.

CHILE.

Undeveloped graphite deposits of possible importance occur near Castro on the island of Chiloe and at Chepueque in the Province of Atacama, Chile.[3]

EUROPE.

AUSTRIA-HUNGARY.

The former Austro-Hungarian Empire led the world in the production of graphite, measured by quantity. This output, however, consisted entirely of armorphous graphite, for the most part of low grade. The production in 1913 amounted to 39 per cent of the quantity of the world's output but to only 9 per cent of the value. The graphite occurs in Bohemia, Moravia, Lower Austria, and Styria, and the reserves appear to be very large. The first two regions are included in the new State of Czecho-Slovakia, and the Lower Austrian and Styrian deposits are in German Austria.

The most productive deposits are those of southern Bohemia. Many others are found in the mountain range that forms the border between Bohemia and Moravia, chiefly on the Moravian side. A group of deposits of probably less value occurs in the lower Austrian hills, on both sides of the Danube. West of Vienna and in the Styrian Alps there are some deposits which at present rank second only to the Bohemian deposits in production.

The Schwarzback-Krumau district, in southern Bohemia, yields about two-thirds of the Bohemian output. The mines have been worked since 1790 and appear to have passed their maximum productivity. However, there is said to be a large area of undeveloped ground. The graphite occurs in irregular lenticular masses of graphite schist interbedded with other metamorphic rocks. The graphite, which as produced contains only about 60 per cent of carbon, is used for foundry facings and the cheaper grades of pencils. The Kollowitz district yields a slightly better grade of graphite, but its output is smaller. The graphite of the Smojanow district, close to the Moravian border, is said to be of poor grade and to carry much pyrite.

The Moravian deposits occur for the most part close to the Bohemian boundary southward from the frontier of Prussia. The most important are those of Altstadt, Kunstadt, Muglitz, and Oels. In

[1] Oakenfull, J. C., op. cit., p. 444.

[3] Miller, B. L., and Singewald, J. T., jr., The mineral deposits of South America, p. 325, 1919

the Altstadt district beds of impure graphite with a workable thickness of more than a meter underlie an area of 10 square kilometers. The graphite is impure and of the amorphous variety, and is used chiefly for foundry facings. The production is probably about 5,000 tons of raw material a year. In the Kunstadt district two beds of graphitic schist have been mined since 1903. The graphite is used in pencil and paint manufacture. The Muglitz district has been known since 1567, and the deposits have been mined more or less systematically since 1847. The graphite occurs in graphitic schist, which has a tenor of 32 to 42 per cent of carbon. The thickness of the bed ranges from 0.5 to 20 meters, in most places 0.75 to 1 meter. The deposit has been developed to a depth of 106 meters. The graphite is used for pencils and foundry facings. Formerly graphite from this deposit was exported to America for the manufacture of pencils. The graphite of the Oels district is similar to that of Muglitz, but the possible reserves are much larger, as three beds, 5, 6, and 11 meters thick, are known. The graphite is said to carry considerable pyrite and is suitable only for pencils and paints.

The graphite deposits of Lower Austria occur in a small area between 65 and 90 kilometers west of Vienna. The graphite is all of poor grade, and the production is small. The only districts of importance appear to be those of Muhldorf and the Dunkelsteiner Wald The Muhldorf deposit consists of a bed of impure graphite from 10 to 40 meters thick associated with crystalline limestone dipping steeply to the southeast. As early as 1855 this bed had been developed to a depth of 160 meters. In 1909, however, only one mine was in operation. The deposit in the Dunkelsteiner Wald consists of graphite lenses of varying purity in crystalline limestone. In part the graphite is crystalline and very pure. After being abandoned for some years the deposit was reopened in 1907 by a Belgian company. The product was used chiefly for the manufacture of pencils.

The graphite deposits of Styria occur in a belt 50 kilometers long extending from Kaiserberg, near Leoben, to Rottenman. The graphite has resulted from the metamorphism of coal beds and in places grades into anthracite. Several beds 6 meters in maximum thickness are worked. The production of the district has shown a steady increase from 400 tons in 1866 to 14,031 tons in 1912. As silica is the only impurity, the graphite, although amorphous, can be used in the poorer grades of crucibles and consequently commands a higher price than other Austrian graphites. The principal use, however, is for foundry facings. The Celli district, in southern Styria, produced a small quantity of graphite between 1902 and 1907.

The Bohemian graphite was formerly used largely for pencils, and considerable quantities were exported to this country before the war, although the bulk of the exports went to Germany. Mexican graphite has now replaced the Bohemian material and will probably continue to do so. The principal value of the Austrian graphite appears to be for use in foundry facings, paints, and similar articles for which a high-grade product is not required.

The Czecho-Slovak and Austrian deposits will have to meet the competition of imported amorphous graphite from Chosen and possibly from Mexico, but most of the deposits appear to be well situated for cheap mining and, especially where a high-grade product is

not required, should be able to supply the demand in central Europe for foundry graphite and possibly in part for the cheaper grades of lubricants. Graphite for crucible use will necessarily be imported. The nearness of the Czecho-Slovak and Austrian deposits to important manufacturing centers will always be a favorable factor.

The following are the most important papers dealing with the Czecho-Slovak and Austrian deposits:

FRANCE.

The only producing deposit of graphite in France is in the Department of Hautes Alpes, not far from the Italian frontier. The graphite is amorphous and the deposit is geologically similar to the Italian deposits. The production, though small, has shown a steady increase in recent years.

As the metallurgic industry of France is likely to grow, it will require a considerable supply of both crucible and foundry graphite. The crucible graphite will probably be supplied from Madagascar, and the foundry graphite also must be imported, as it does not seem probable that the Hautes Alpes deposit is capable of meeting the demand. The most convenient source of amorphous graphite for France appears to be Italy; possibly Czecho-Slovakia and Austria are also sources of supply, and the poorer grades of the Madagascar graphite, though not suitable for crucible use, are likewise available.

There are undeveloped graphite deposits in the departments of Arriège and Rhone.

GERMANY.

Germany possesses only one graphite region of importance, the Passau district in eastern Bavaria, close to the Austrian frontier. The graphite is of the flake variety and occurs in lenses in gneiss, carrying normally 20 to 25 per cent of graphite. These lenses are from 10 to 20 meters thick and are probably workable to a depth of 70 meters, owing to deep weathering. The deposits have been mined in a small way for centuries, but only since 1909 have modern mining methods been introduced. The deposits are favorably situated with respect to the supply of the famous Klingenberg clay for manufacture of crucibles, and the first graphite crucibles were manufactured in Passau. Some years prior to the war, however, Ceylon graphite had largely replaced the Bavarian graphite for crucibles and the local graphite was used chiefly for lubricants and foundry facings. The methods of mining and milling were antiquated and wasteful.

After the war began crucibles were perforce made with Bavarian graphite, and it is probable that in future improved methods of mining and milling will allow a larger use of the material than formerly; thus Germany may remain to a certain extent independent of foreign sources. Amorphous graphite can probably most readily be supplied to Germany from Czecho-Slovakia. Graphite, probably of the amorphous variety, occurs at Friedrichroda, near Gotha, but is not mined.

In 1918 old graphite mines at Tirschenreuth, in northeastern Bavaria near the Bohemian frontier, which had been idle since about 1860, were reopened.[1]

During the war there has been a shortage of graphite in Germany in spite of the output of the Bavarian, Bohemian, and Austrian mines. Numerous substitutes were used for foundry facings, and graphite was recovered from old crucibles by means of hydrofluoric acid.

The following publications contain more detailed descriptions of the German graphite deposits:

Cirkel, F., Graphite, Canada Dept. Mines, Ottawa, 1907.
Dammer, B., and Tietze, O., Die nutzbaren Mineralien, vol. 1, 1913.
Stutzer, O., Die wichtigsten Lagerstätten der Nicht-Erze, vol. 1, 1911.

——— Ueber einige Graphitlagerstätten: Zeitschr. prakt. Geologie, 1907, pp. 286–290.

[1] Zeitschr. angew. Chemie, vol. 31, p. 210, 1918.

ITALY.

The Italian deposits occur on the east flank of the Alps near Pinerolo, Province of Turin; in the Ligurian Mountains in the Bormida Valley, province of Genoa; and in the Province of Cuneo.

The graphite is amorphous and in places grades into the anthracite from which it was metamorphosed. It is apparently similar to the Austrian graphite and is used for foundry facings and lubricants. The beds attain a maximum thickness of 3 meters.

So far as known Italy has no supplies of clay suitable for the manufacture of crucibles and hence must depend on crucibles imported from France, Germany, or England, or both clay and crucible graphite must be imported. On the other hand, the production of amorphous graphite is in excess of local needs and formerly went chiefly to Germany, now to England and France. Unless Italian metallurgic industries should expand greatly there will be, at present rates of production, a considerable surplus available for export. Competition from Madagascar and Chosen can probably be met successfully owing to cheaper freights.

The following publications contain more detailed information on the Italian graphite deposits:

Novarse, V., I giacimenti di grafite delle Alpi Cozie: R. com. geol. Italia Boll., vol. 29, pp. 4–36, 1898. English abstract in Mineral Industry for 1900, vol. 9, p. 380, 1901.

Rivista del Servizio minerario, annual reports, 1881–1915.

Stutzer, O., Die wichtigsten Lagerstätten der Nicht-Erze, vol. 1, pp. 43–45, 1911.

NORWAY.

The production of graphite in Norway has hitherto been insignificant. According to recent reports, however, preparations are being made to work deposits in the Skaland district, northern Norway, on a large scale.[1] Apparently these deposits may be expected to furnish Norwegian requirements and allow a surplus for export.

PORTUGAL.

No graphite is produced in Portugal, and as it is not an important manufacturing country the demand is probably small. The deposits of the Almonaster district, in Spain, have been found to extend into the Contienda de Maura, a small area of disputed territory along the frontier, and in all probability enter Portugal. No developments are known, however.

RUMANIA.

Notices in the German technical press during the winter and spring of 1918 contained jubilant references to the discovery and exploration of immense graphite deposits in Rumania.[2] These deposits lie on the southern slope of the Carpathians at Baia de Fier and in the Oltetz Valley in western Rumania, apparently not far from the former Hungarian frontier. An area of 10,000 hectares was leased from the Rumanian Government for a period of 75 years, the product to be

divided between Germany and Austria. Development work began in February, 1918.

RUSSIA.

Russia, particularly Asiatic Russia, possesses large reserves of graphite, but so far as data are available the production has been insignificant. The famous Alibert mine, near Irkutsk, in eastern Siberia, formerly produced a considerable quantity of pencil graphite, and this graphite has also been used to a small extent in the manufacture of crucibles. The other important deposits, those of Yenisei River in eastern Siberia [1] and those in the northern part of the Caucasus Province, probably consist of amorphous graphite. Some work was done on the Yenisei deposits in 1908 and 1909.[2] In the extreme eastern cape of Siberia there are graphite deposits similar to those of the Nome Peninsula, Alaska. The availability of the Russian deposits depends on the possible future development of Russia as a manufacturing country, for, unless the deposits should prove of exceptionally high grade, difficulties of transportation would reduce their availability for foreign use.

At the outbreak of the war the Morgan Crucible Co. established a crucible factory in Russia, and a large quantity of Ceylon graphite was imported. It is not known whether the clay was also imported or whether suitable local supplies were obtained.

The only deposit in European Russia concerning which any information is available is that of the Dzimarsk district, in the Caucasus.[3] Here graphite, presumably amorphous, occurs in large beds or lenses with an average thickness of 1 meter and a known extension of 1,500 meters. The carbon content ranges from 30 to 60 per cent.

Other occurrences are as follows: [4]

Pudosch district, near Onegasee, Olenetz government; Jelantschik district. southern Ural Mountains, granite boulders containing high-grade crystalline graphite; Zytomierc district, near Mecherzynce, Volhynia; near Mariupol, Jekaterinslav district, Ukraine, with a reported production of 2,000 tons (in 1913)[5]; Kumi Maggi, on the north shore of Lagoda Lake, Finland; Ekaterinburg; Miask; and Slatust. Graphite for foundry facings was recently mined at Boevsky, in the Ural Mountains.[6]

SPAIN.

Spain's recent production of graphite began in 1915 with an output of 33 metric tons, which increased to 1,240 tons in 1916, and gives promise of considerable future development. The principal district is near Almonaster, in Huelva Province.[7] The graphite is of the flake variety and occurs in graphitic schists. The portion now being developed is a belt 10 miles long and half a mile wide in which lenses

containing 10 to 20 per cent of graphite are mined. The graphite schists, however, are known to extend from Alojao to Aroche and occur also in the Contienda de Maura, a disputed area between Spain and Portugal.

Other occurrences are as follows:[1]

Ijualija district, Sierra de Ronda, Malaga Province, amorphous; Mirabella district, near Ronda, Malaga Province, crystalline; between 1750 and 1800 this district produced 9,476 tons, but the deposit is apparently exhausted. Labour and Barbarissa Mountains, Spanish Pyrenees, Santander Province, reported small production prior to 1911.

With future development of the local iron industry the Spanish graphite deposits will probably become more important. The present production appears to be largely the result of Spain's comparative isolation during the war. Prior to the war Spain's requirements both for crucibles and graphite were supplied from Germany.

SWEDEN.

The Norberg deposit [2] in central Sweden appears capable of furnishing graphite suitable for crucible use. The annual production for the last few years has not exceeded 100 tons. In Lapland, near Vittangi, about 60 kilometers east of the Kiruna Railway, there are large undeveloped deposits of amorphous graphite.[3] These should become important as a source of graphite for foundry use as the Swedish iron industry develops.

During the war the manufacture of crucibles was begun in Sweden, but it is not known how far local material was employed.

SWITZERLAND.

A deposit of amorphous graphite at Iserables, Canton Wallis, Switzerland, near the French frontier, has been mined in a small way. The last recorded production was 3,000 tons in 1899, but it is possible that there were developments during the war. The material is similar in type to other Alpine graphite deposits and grades into anthracite. Crystalline graphite was formerly worked [4] at Roverado, Canton Graubunden, near the Italian frontier.

TURKEY.

Graphite is said to occur in the Dardanelles peninsula, but nothing is known as to the extent or value of the deposits.[5]

UNITED KINGDOM.

The famous Borrowdale deposit, in Cumberland, England, formerly furnished a very pure crystalline graphite which was used in the manuture of pencils. The deposit was discovered in 1564 and was worked

[5] Dammer, B., and Tietze, O., op. cit., p. 68.

extensively between 1788 and 1833. The last production was made in 1876, and the deposit is supposed to be exhausted.

Near Cumnock, in Ayrshire, there is a bed of coal locally altered to amorphous graphite by an intrusion of dolerite. This deposit was worked on a small scale between 1750 and 1848. It was reopened for a short time in 1908, and 101 tons of graphite, used for foundry facings, was extracted.

A seam of graphite from 1 to 3 feet wide occurs near Invergarry, in Inverness-shire. A production of two tons was obtained from this seam in 1825 and it is considered that deposit may prove worthy of development.[1] Graphite is also reported from Montgomeryshire and Merionethshire.

As the iron and steel industry of England is of great magnitude, the country is a large consumer of graphite. The crystalline graphite required is imported from Ceylon and Madagascar, and the amorphous graphite from Chosen and Italy. Supplies of clay suitable for making crucibles are available.

ASIA.

CEYLON.

Until recently Ceylon was the largest producer of high-grade crucible graphite in the world. In 1913 the output of this island as measured by tons was 20 per cent of the world's production, but by value it amounted to 64 per cent. Lately the output has been surpassed in quantity though not in value by Madagascar. Bastin [2] has summarized the available descriptions of the Ceylon graphite deposits as follows:

> The following account of the graphite deposits of Ceylon is condensed from a paper[3] published in 1911. Those desiring more complete information should consult the original paper and its accompanying bibliography.
>
> The graphite deposits of Ceylon [see fig. 54] are of especial interest to Americans because most of the graphite used in this country comes from that island and because the United States has for many years been the largest consumer of the Ceylon material. Much has been printed in regard to these deposits, but it is widely scattered through publications in various languages which are not readily accessible to the American public. The writer has, therefore, summarized the more important facts which are on record, with apologies for any errors which may have crept in on account of his lack of personal knowledge of the island.
>
> Although their existence was known in early times and mentioned in print as early as 1681, the graphite deposits of Ceylon were not exploited until some time between 1820 and 1830. Joseph Dixon is said to have imported a small quantity into the United States in 1829, but it was not until 1834 that the industry assumed any commercial importance. From that time to this, as a result of the growth of metallurgical industries and the resulting demand for refractory materials, the industry has developed rapidly, until at present graphite is subordinate in value only to tea and the products of the cocoanut palm among the exports from the island. * * *
>
> From the early days of the industry up to 1901, Great Britain consumed more Ceylon graphite than any other country. Since 1901 the United States has assumed the first place, with Great Britain second until 1909, when Germany took second place. * * *

With the exception of a limited amount of graphite mining done on tea estates, the industry is in the hands of native Sinhalese. It has been estimated that the various processes of mining, sorting, "curing," packing, and shipping graphite, as well as the making of barrels in which it is exported, provide employment for about 50,000 men, women, and children.

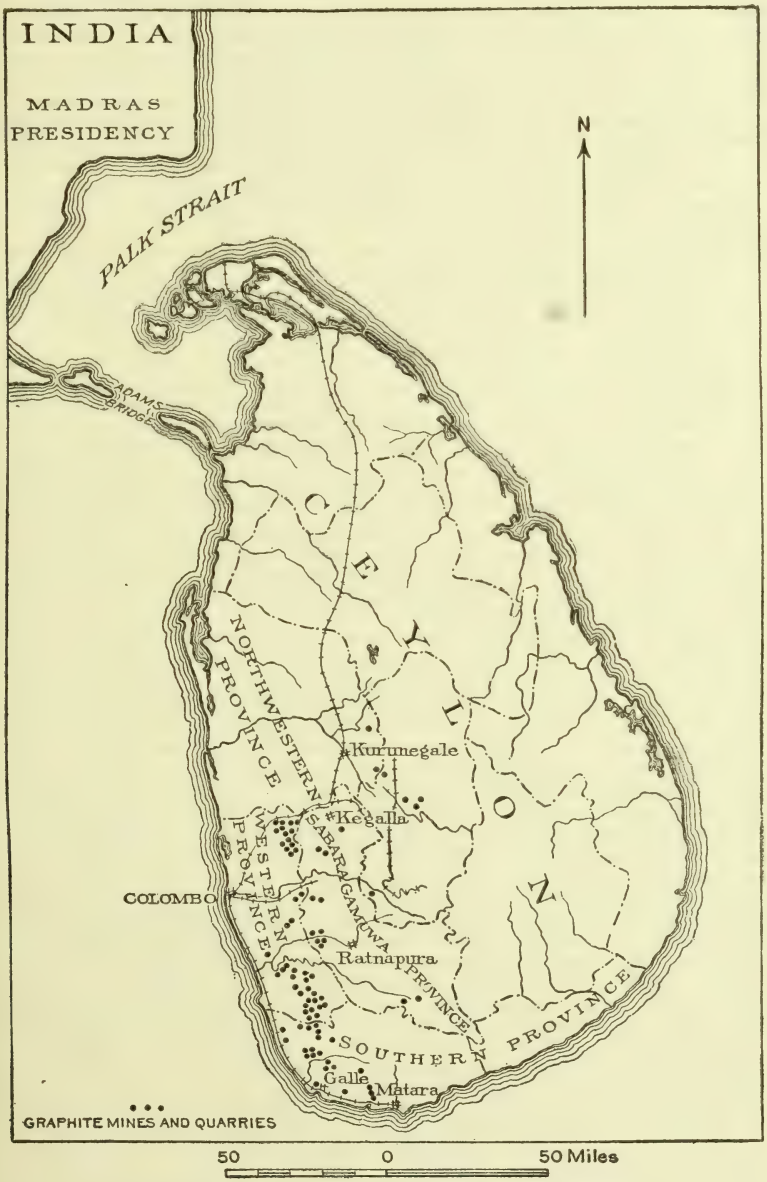

FIGURE 54.—Map showing location of Ceylon graphite deposits.

The island of Ceylon is just off the southern point of the peninsula of British India, the channel between being nowhere deep enough for the passage of large ships. The island is more or less pear-shaped in form, and has a length from north to south of about 275 miles and a maximum width of about 135 miles. A railroad extends the

entire length of the island, with branches into the central interior. Colombo, the capital and principal seaport, is on the western coast, and is the port from which nearly all of the graphite is shipped. A small quantity is shipped from Galle.

The island of Ceylon may be divided into two natural divisions—a mountainous region of crystalline rocks, which forms the southwestern part of the island, and a lowland area made up of coral limestones and marine sands of much later origin to the north and east. In the mountainous region there are 10 peaks which rise to elevations of over 7,000 feet, the highest being 8,296 feet. This region covers about one-fifth of the area of the island. The principal mines are in the south-central and southwestern parts of the island, and all are within the mountainous region.

The most abundant rocks of the mountainous crystalline area are gneisses of both light and dark varieties. Intimately interbanded with the commoner types of gneiss in bands varying from a few inches to hundreds of yards in width are crystalline limestones, many of which are dolomitic. The origin of the gneisses is not certainly known, but the presence of beds of crystalline limestone will be regarded by most geologists as proof that a part of them at least are metamorphosed sediments. Others are probably altered igneous rocks.

The groundmass of gneissic rocks has been intruded by several types of massive igneous rocks, among which granite pegmatites are conspicuous. The graphite is present locally in small amounts, disseminated in the crystalline limestones and some of the gneisses. The commercially important deposits, however, are all veinlike in character and were deposited along fracture planes in the rocks. They were thus formed distinctly later than the rocks which they traverse. In most of the graphite districts the main veins parallel the foliation planes of the gneisses, thus striking northwest and southeast. In the Kurnegale district, on the other hand, the principal veins strike northeast and southwest, parallel to a system of joint fractures. In any pit or series of pits there is usually a single main vein or several parallel veins following one of these directions of fracturing and sending off minor veins or stringers along the less prominent set of fractures. In some places the extent of the veins along their trend is so slight that they may be more correctly described as lenses. In other places veins of considerable width may contract to mere seams, only to widen again when followed farther. The width of the vein varies from less than an eighth of an inch to several feet, and some as narrow as 2 or 3 inches are worked. The walls are usually sharply defined, and the bordering rock is not impregnated with graphite to a distance of more than half an inch from the veins.

In small veins the graphite usually forms an aggregate of parallel platy needles set at right angles to the vein wall. In the larger veins most of the graphite shows a coarse platy structure, though the needlelike structures may be developed in a band from a few millimeters to 2 or 3 centimeters across next the walls or next masses of wall rocks inclosed in the vein. The needlelike aggregates are in high favor commercially, because of their highly fibrous structure and are known as "needle lump." Spherulitic aggregates of graphite plates are of occasional occurrence.

Usually the veins consist almost entirely of graphite, but sometimes other minerals occur in important amounts. Pyrite is almost always present either disseminated between the individual flakes or needles or concentrated in a more or less definite band in the central portion of the vein. Occasionally a pyrite crystal is penetrated by graphite flakes. Quartz, usually milky, often forms a part of the vein, sometimes occurring as a central band. In a few places rosettes of graphite flakes occur in the quartz, and in other places quartz grains lie between flakes of graphite. Quartz and pyrite are the only accessory minerals which are nearly always present, but occasional minerals are biotite, orthoclase feldspar, pyroxene (usually augite), apatite, allanite, and rutile. The last is sometimes developed along cleavage planes in the graphite crystals. In one mine a remarkable cavity or "vug" was encountered, which was about 15 feet high, more than a yard wide, and oval in section. Its walls were lined with flaky graphite, and similar material filled its lower portion. In some of the graphite veins slight movements subsequent to their formation have bent the graphite flakes or crushed them to an earthy mass and developed slickensided fracture surfaces.

The graphite is mined either from open pits or through vertical shafts connecting with underground workings. The majority of mines are not deeper than 100 feet, though a few go as deep as 400 or 500 feet. On account of the heavy rainfall, water is one of the chief obstacles in deep mining. In a few mines steam pumps and hoists are employed, but as a rule the mining methods are still crude, the acme of mechanical ingenuity being reached in a windlass operated by five or six men for hoisting the graphite in a sort of tub. The workmen usually ascend and descend by means of rough wooden ladders, tied with jungle ropes and rendered exceedingly slippery by the graphite dust and water.

The mineral as it comes from the pits may contain as much as 50 per cent of impurities, mostly in the form of quartz and wall rock. It is conveyed in bags to a dressing shed, where it is picked over and the impurities reduced to 5 or 10 per cent.. It is then packed in barrels for transportation to Colombo or Galle. At these ports it is unpacked and submitted to further treatment, known as "curing." The graphite merchants have fenced yards or "compounds" for the final preparation of the graphite for the market. In the methods of "curing" there is some diversity, but the first step is usually to set aside the large lumps and to pass the remainder through stationary screens of several different sizes of mesh. The large lumps and the screened pieces are then broken with small hatchets by Sinhalese women to remove the coarser impurities, such as quartz, and are then rubbed up by hand on a piece of wet burlap and finally on a piece of screening to give them a polish. Finally, various grades coming from several mines or differing in size or texture are blended to meet the requirements of purchasers, a process requiring skill and long experience.

The poorer material is usually beaten to a powder with wooden mauls or with beaters shaped like a rolling pin, and is then sorted into different grades. In some establishments the impure grades are washed in a tub or pit. In this process the mineral is placed in saucer-shaped baskets, and by a circular "panning" motion of the immersed baskets the graphite particles are thrown off into the pit, while the heavier impurities, especially pyrite, remain behind. To separate the very fine material, the powdered graphite is placed in a basket with somewhat the shape of a large dustpan. The contents of the basket are thrown into the air, and the heavier particles fall back into the basket, while the finer material is blown forward and falls on the floor.

The graphite-mining industry in Ceylon was in a very depressed condition during 1914, because of shortage of labor and of the unusually heavy rains, which interfered with mining operations. This depression was aggravated by the embargo imposed in October, 1914, on the exportation of graphite to countries other than those of the allies. After the modification of the restrictions on exports to the United States, about the middle of 1915, and because of the greatly increased demand for graphite for crucibles to be used in the manufacture of munitions, most of the mines resumed operations.

The years 1916 and 1917 were years of great prosperity for the Ceylon graphite industry. The demand for Ceylon graphite by American crucible makers increased greatly, and the best grades of lump, which prior to the war did not bring more than $150 a long ton, sold as high as $500 a ton. The competition of the increasing output of Madagascar was scarcely felt, as the Madagascar graphite went chiefly to the British and French markets, whereas America took most of the Ceylon exports, 75 per cent in 1916 and 81 per cent in 1917. The principal drawbacks were the increased cost of mining, due to working at greater depth, and the high freight rates, which spoiled the market for the lower grades, such as dust and flying dust.

The freight rate in effect on graphite shipped from Colombo to New York in 1916 was $34.80 a ton, plus a war surcharge of 50 per cent on shipments by way of Cape of Good Hope. In addition to this there was a supplemental charge of 10 per cent on the total of the gross freight and surcharge.[1]

Another important factor affecting the cost of Ceylon graphite was the rise in price of casks and hoop iron. Barrels advanced in price from $1 in 1914 to $2.50 in 1916, and hoop iron went up in price from $50 to approximately $150 a ton.

The former export duty on graphite was $1.62 a ton; this was changed on July 22, 1916, to 3 per cent ad valorem, thus increasing the cost to the consumer.

[1] Commerce Repts., Sept. 4, 1916, p. 42.

Toward the end of 1917 the American demand fell off and the prices declined somewhat, resulting in a decrease in output.

The graphite mining is largely in the hands of native Ceylonese, the majority of owners being men of small means with labor forces not usually numbering more than 20. Such owners must rely on an immediate sale of their graphite, and any marked fluctuations in the market will cause them to shut down or open up their mines. Thus on June 30, 1917, when the market was good, 1,288 mines, employing 19,912 men, were in operation, as compared with 764 mines at the end of the year, employing 15,379 men. The small mines are obviously the first to be shut down in case of market depressions.[1]

The American import restrictions put into force in the spring of 1918 proved a severe blow to the Ceylon graphite industry. The price of lump graphite fell to less than half the former price and lower grades were almost unsalable. Exports in 1918 were less than in any year during the preceding decade except 1914, and in addition large stocks accumulated for which there was little demand after the armistice.

Prices early in 1919 were reported as follows:[2] Lump, $115 to $225 a long ton; chip, $65 to $150; dust, $20 to $100; and flying dust, $13.

Costs of mining rose greatly during the war, but it is said that with the installation of improved machinery and the development of the mines to greater depths an annual production of 30,000 tons can be maintained for many years.[1]

The following table shows exports from Ceylon for 1913–1918. In addition to the graphite directly imported by the United States a portion of that sent to Great Britain during 1914 to 1918 was consumed in this country.

Graphite exported from Ceylon, 1913–1918, in short tons.

Country.	1913[a]	1914[a]	1915[b]	1916[b]	1917[b]	1918[b]

[a] Ceylon Blue Book. [b] Ceylon Chamber of Commerce Repts.

CHOSEN (KOREA).

Chosen graphite was formerly used quite extensively in this country, but in 1918 very little was imported on account of import restrictions.

[1] Commerce Repts., Aug. 9, 1918, p. 535. [2] Idem, Mar. 25, 1919, p. 474.

The graphite industry of Chosen is of recent date, the first exports having been made in 1903, and it was not until 1907 that exports reached 1,000 tons a year. The production appears to have increased steadily, except for a slight decrease in 1915, due to high freight rates, until 1917, when there was a sharp decline in production caused by the partial loss of the American market owing to Mexcian competition. It is estimated that out of a production of 6,500 long tons in 1917, only 4,500 tons was exported. Prices, which in 1916 were more than double those of 1913, had fallen back to the pre-war level. In the spring of 1918 Chosen graphite was excluded from America by the import embargo and, although statistics are not available, it is probable that production declined heavily as the Japanese demand does not exceed 3,000 tons annually, even under war conditions.[1]

Most of the Chosen graphite is of the amorphous variety and is used principally for foundry facings. It comes chiefly from the central and eastern part of the kingdom and is shipped from the port of Fusan. The graphite occurs as beds and irregular lenses. At one of the mining localities in the Kyeng-Sang district three seams of graphite with maximum widths of 78, 18, and 48 feet have been mined.[2]

There is also a small production of crystalline graphite in the northern part of the country. This material is said to occur in thin flakes similar to the crystalline graphite of Alabama.[3] So far as known very little of this material has come on the American market.

JAPAN.

Japan produces a small quantity of graphite, apparently both amorphous and crystalline. Little information is available regarding the deposits. The graphite imported into this country from Japan is probably mined in Chosen.

INDIA.

Formerly graphite similar to that of Ceylon was mined in the State of Travancore, in southern India, but with increasing depth the mines became unprofitable, and production, which had ranged from 2,000 to more than 4,000 tons a year, ceased in 1911. In recent years some graphite has been produced in Rajputana and Kalahandi. Undeveloped deposits occur in the Ruby Mines district of Burma.

CHINA.

Graphite is reported from many localities in China, but none of the deposits have been developed.

MALAY STATES.

Graphite deposits of considerable extent have lately been reported in the Malay States but nothing definite is known with regard to them.

AFRICA.

MADAGASCAR.

The graphite industry in Madagascar has made remarkable progress in recent years. The industry began in 1907 with a production of 8 metric tons, and the output in 1917 amounted to 35,000 metric tons, exceeding even the Ceylon exports. The graphite is of the flake variety and is very similar in appearance to the best American flake graphite. It occurs in graphitic schist and gneiss throughout the area of older crystalline rocks, which occupy over two-thirds of the surface of the island.

The following description of the Madagascar deposits is reprinted from the Geological Survey report on graphite for 1913:[1]

An interesting account by P. Contanciel of the occurrence of graphite in Madagascar was published in a French journal [2] in 1912. The parts likely to be of interest to Americans are summarized below. For exact locations, maps, and diagrams, the reader is referred to the original article.

The known occurrences of graphite in Madagascar are confined to the area of ancient crystalline rocks that forms the eastern half of the island. This crystalline tract is in turn divisible into a high plateau region and a lowland tract. Graphite occurs in each but in a somewhat different manner.

GRAPHITE IN THE HIGH PLATEAU TRACT.

The climate of the plateau tract is much less humid than that of the lowlands and vegetation is less prolific. The plateau is in many places separated from the lowlands lying east of it by a steep escarpment whose heavily forested slope extracts much moisture from the prevailing easterly winds.

Because of the climatic features rock exposures are much more abundant than in the lowlands, and there are no deep deposits of "laterite," that is, soil resulting from prolonged rock decay. The graphite deposits are, therefore, strictly bedrock deposits. In the commonest type the graphite is a constituent of a graphitic schist and forms flakes lying between grains of quartz or altered feldspar. Biotite or black mica is sometimes present, but in general is not abundant in the highly graphitic schists. The graphitic schists discovered up to 1912 occur in three principal bands, two of which pass near Tananarivo, the capital of the island. Most of the deposits now known have been covered by claims, but development had at the time this article was written not advanced beyond the "prospect" stage. Their exploitation would involve the crushing of the rock and the separation of the graphite by washing or other means from the feldspar, quartz, and mica with which it is intergrown.

A second mode of occurrence of graphite in the plateau tract is in so-called flat veins (filons couchés). Their exact character is not quite clear from M. Contanciel's descriptions. He states that they lie parallel to the foliation of the schists, and that some of them attain a thickness of as much as 20 meters.

Their graphite content is higher than that of the ordinary graphitic schists, and may reach 30 per cent, though seldom more. They have been the object of serious exploitation at several places, the excavations commonly being open pits, though in a few places shafts and galleries have been driven. The open pits seldom exceed 25 meters in depth and are all, therefore, in more or less decomposed material which is easily excavated.

The Tsarazafy concession northwest of Tananarivo is an example of a property worked by underground methods. The method of concentration employed at the Tsarazafy concession is described as follows: The crude material, which seldom contains more than 30 per cent of graphite, is first washed in tubs by women laborers along the river bank. By this washing the graphite concentration is raised to about 50 per cent, much being lost in the process. The material is next spread on hearths heated by brush fires, to dry, and then fed to a series of screens with round openings 3, 2, and 1 millimeters in diameter. The oversize from the 3-millimeter screen is sent to crushing rolls and then again passed over the screens. The sized product from the screens goes to winnowing machines, somewhat similar to those used in

[1] Bastin, E. S., U. S. Geol. Survey Mineral Resources, 1913, pt. 2, pp. 242–244, 1914.
[2] Contanciel, P., Note sur les graphites de Madagascar: Soc. indust. min. Bull., November, 1912, pp. 505–530.

vanning corn. The products of these machines are tailings that are discarded, middlings that are re-treated, and two sizes of graphite concentrate (1 to 2 millimeters

FIGURE 55.—Map showing location of Madagascar graphite deposits.

and 2 to 3 millimeters). The vanning is not very efficacious in separating the fine rock dust and much of it is eliminated by further screening. The final product,

averaging about 80 per cent graphite, is only 5 to 10 per cent by weight of the rock mined. After sacking it is ready for shipment. Electric power for the mill is supplied from a power plant at a falls 2 kilometers distant. The cost of mining and milling by this process is about 90 francs ($17.37) per metric ton of concentrate produced.

The native process is still simpler, and at the Louys mine, at Isaha, is carried on as follows: A laborer breaks the lumps of crude material with a mallet or a club and throws the material into a cubical tub 0.6 meter in diameter. A current of water enters at one side of the tub and leaves at the other, and the same laborer agitates the material in the tub with a spade. The overflow from the tub goes into a slightly inclined wooden trough 4 meters long, 0.3 meter wide, and 0.3 meter deep, whose lower end is half closed by a board 0.15 meter high. The agitation in the tub tends to float off the slime, while the sand and most of the graphite remain behind. Whatever graphite floats off is caught in the trough. The washed mixture of sand and graphite is dried in the sun on floors and then passed to screens of 4, 8, 12, and 16 meshes per centimeter. After the screening the several sizes are sacked. The product averages about 70 per cent graphite and forms about 2 per cent by weight of the rock as mined. The cost of mining and milling is about 100 francs ($19.30) per metric ton of concentrate produced.

GRAPHITE IN THE LOWLAND TRACTS.

The lowland tract, east of the plateau tract, is characterized by great humidity and by prolific vegetation, which completely masks the bedrock. The soil resulting from rock decay ("laterite") is deep and in it the graphite occurs. The original rock before decay was probably similar to the graphitic schist of the plateau tract. The process of rock decay has served to increase somewhat the percentage of graphite by removing some of the more soluble constituents of the rock, and has yielded an incoherent and easily excavated material which requires no crushing. The greater ease and cheapness with which the graphite deposits of the lowlands can be worked, as compared with those of the plateau, is counterbalanced to some extent by transportation difficulties. Real roads are practically lacking, and if constructed are almost impossible to maintain. It is hard to conceive how difficult it is for the natives themselves to cover even small distances along the paths that are pompously called "roads," and all transportation in our day, at least, must be on the backs of men. Because obscured by vegetation, the deposits are less easily located and followed by the prospector than in the plateau tract.

According to another description[1] the rock weathering in the plateau country, where most of the productive mines are situated, extends to depths of 150 to 200 feet. The graphite forms irregular lenticular deposits, and both flake graphite and the fibrous variety are present.

A recent article by Shelley[2] gives more detail concerning mining methods and costs, and this portion of the article is summarized below.

The graphite generally occurs in partly decomposed gneiss, associated with soft micaceous or chloritic schist. The bulk of the graphite is in the form of thin flakes from one-eighth inch in diameter down to the finest dust. Some very pure lump and fibrous graphite is found, but seldom in sufficient quantity to render separate treatment profitable. As dug out and taken to the dressing floors the ore contains 60 per cent of graphite. [This is a far higher tenor than is given in other descriptions.] Of this only about one-third is recovered by present methods. Of the recovered portion 60 per cent, with a carbon content reported to be from 90 to 96 per cent, is suitable for the manufacture of crucibles, the remainder being fine dust. Some deposits are at present unworkable owing to their high percentage of iron

[1] Bawden, E. R., Some observations on the graphite deposits of Madagascar and Africa: Chem., Met., and Min. Soc. South Africa Jour., vol. 13, p. 258, 1912.

oxide and mica. The deposits are usually worked by open cuts, except in a few places, where they are opened by drifts into the sides of the hills. After removing the overburden and intervening partings, the crude graphite is dug out by spades and removed in barrows and baskets to the sluices, which are at a lower level, close to the mine.

The sluices are rectangular wooden boxes, 36 inches square by 24 inches deep, let into the sloping ground on three sides. On the lower side there is a sliding door, which can be raised to permit the discharge of the débris. The boxes are kept filled to a depth of 8 inches. A steady stream of water, equal to about 8 gallons a minute, is led into each box, and the material is constantly stirred with a wooden paddle. In this way the fine sand, mud, and flake graphite are kept in suspension and flow over the lip of the box into a small trough with a 60-mesh screen nailed to the bottom. The muddy water and fine sand pass through the screen, while the flake is retained. The flake is pushed forward by the gentle waves produced by the paddle and is discharged into a small box. The washing process requires two operations, the one to separate the bulk of the coarse material and the other to separate the particles of fine quartz and feldspar and obtain a clean product. Each gang produces about 1 hundredweight a day. The waste contains a quantity of large flakes and chips. The washed graphite is dried in the open on mats.

The next processes are those of vanning and sifting and are performed by women. The vanning consists in tossing up the material so as to bring the dust and sand to the outside edge of an oblong wooden tray and tipping it over the side by a dextrous movement of the wrists. It is afterwards screened into three grades of 20, 40, and 60 mesh. Satisfactory material is credited to the worker at the rate of 10 centimes a kilogram (slightly less than 1 cent a pound). Rejected material is returned to undergo further treatment.

At a mine with an average yield of 25 metric tons a month, costs are about 225 francs a ton (2 cents a pound). Costs of transportation are estimated at 97.50 to 130.50 francs a ton, and shipping charges and freight to London from 71.50 to 92 francs. Other costs, including incidental expenses, stores, taxes, etc., are estimated at 30 francs a ton, and the total cost, c. i. f. London, between £17 and £19 a ton, (between 3.8 and 4.2 cents a pound, at normal exchange).

De Pritzbauer[1] in a recent article states that the graphite tenor of the ore in favorable places is 25 to 30 per cent, but that 10 per cent ore is considered workable. According to this article the average cost at the mines scarcely exceeds 100 francs a metric ton, but transport charges to Tamatave are between 350 and 400 francs.

According to Bonnefond,[2] if the base price of 600 francs a metric ton (5.25 cents a pound at normal exchange) for 90 per cent material f. o. b. Tamatave is maintained, the productive capacity of Madagascar is at least 50,000 tons a year. He estimates that there is 2,000,000 tons of merchantable graphite in sight, capable of being mined by open-cut methods, and an additional 7,000,000 to 8,000,000 tons, which can be exploited to a depth of 100 meters below the surface.

[1] De Pritzbauer, L., L'avenir de Madagascar: Chimie et industrie, vol. 1, pp. 679–680, 1918.
[2] Bonnefond, F., Les mines de Madagascar en 1918: Soc. ing. civils de France Bull. 7 and 8, pp. 366–367, 1918.

After several years of exceptional prosperity the graphite industry in Madagascar is now suffering a setback consequent upon overproduction. During 1917 the production greatly exceeded the exports, and it is estimated that by February, 1918, stocks of about 15,000 tons had accumulated in the island, in addition to large quantities in Marseille, France. Graphite was exported only under license of the French Ministry of Armament. The principal purchaser was the Graphites Maskar, a subsidiary of the Morgan Crucible Co., of London. About half the exports in 1917 went to England and the remainder to Marseille, whence a part was reexported to America.

In 1917 the graphite industry gave employment to several thousand white men and about 200,000 natives, and 4,064 claims had been taken up. By the summer of 1918, however, production had nearly ceased. The import restrictions of the United States had excluded graphite from the American market, further imports into France were prohibited except by special license, and the Morgan Crucible Co., the principal buyer, had reduced its purchases to one-sixth of the former amount and had given notice that no more would be bought after July 1, 1919.[1] In May, 1919, stocks of Madagascar graphite at Marseille were reported to amount to 12,000 to 14,000 metric tons,[2] which together with the stocks in Madagascar, amounting to 25,000 metric tons in January, 1919, must be absorbed before mining can return to its former basis. In November, 1918, the Union des producteurs de graphite de Madagascar offered to furnish annually to the United States 15,000 to 20,000 metric tons of flake graphite at 600 francs a ton, f. o. b. Tamatave.

The Madagascar government has authorized the exportation to the United States during the first half of 1919 of 15,000 tons of graphite. It is doubtful, however, whether trade conditions in this country would allow the absorption of more than a small part of this.

The production in 1918 was 16,000 metric tons and during the first nine months of 1918 exports of graphite from Madagascar amounted to 15,014 metric tons, valued at $1,303,768.[3]

SOUTH AFRICA.

A small quantity of graphite is produced annually in the Transvaal.[4] The deposit now exploited is in the eastern portion of the Zoutpansberg district. It is in the form of a lens with an average thickness of 10 feet, and has been proved along the strike for a distance of 250 feet. The footwall is formed by decomposed pyroxenite and is overlain by schistose quartzite dipping 55° S. The pyroxenite incloses crystals and flakes of graphite and may be genetically related to the deposit. The greater part of the lens consists of amorphous or finely crystalline massive graphite, which is traversed by narrow veins of flake graphite. The amorphous graphite is fairly pure except near the hanging wall, where it is mixed with arenaceous matter. A series of representative samples assayed from 50 to 90 per cent carbon.

[4] Wagner, P. A., Graphite in South Africa: South African Journal of Industries, February, 1918. Abstract in Mining Magazine, pp. 320–321, June, 1918.

The graphite is shipped to Johannesburg and there made up into various graphite products for which there is a good local demand.

The paper cited above mentions other graphite deposits in Transvaal, Southwest Africa, Natal, and southern Rhodesia, none of which has yet proved worthy of development.

EAST AND CENTRAL AFRICA.

Graphitic schists of high graphite content and vein graphite are reported to occur at several places in the Nyasaland Protectorate,[1] British East Africa,[2] and German East Africa.[3]

PORTUGUESE EAST AFRICA AND BELGIAN KONGO.

The available descriptions of graphite in Portuguese East Africa [4] and the Belgian Kongo [5] indicate large reserves of high-grade graphite, but lack of cheap transportation facilities has hitherto prevented development.

AUSTRALIA AND NEW GUINEA.

Deposits of flake graphite of probable commercial importance occur in Eyre's Peninsula, in South Australia.[6] The graphite occurs in schists which are associated with quartzite and lime-silicate rocks and intruded by pegmatitic granite. The flake close to the surface carries much limonite and grit, and a clean product is not easily obtainable. At depths of 10 to 20 feet the flake is clean, and the prospects are considered favorable for the development of large bodies of workable ore. The most promising part of the region appears to be the Uley district, near Port Lincoln. Here rich streaks contain as much as 31 per cent of recoverable flake, and it is estimated that at least 7 per cent can be recovered over a large area. The estimated costs of mining and milling are given as 16 shillings a ton of ore, which, on a basis of 7 per cent recovery, would equal about 2½ cents a pound of graphite. In order to encourage graphite production, the State of South Australia has offered a bounty of £1 per ton on all graphite produced prior to June 30, 1919. Graphite deposits at Mount Bopple,[7] in Queensland, were formerly worked in a small way. The graphite is amorphous and is formed from coal beds graphitized by granitic intrusions.

Graphite occurs in New South Wales at Wilson's Downfall,[8] and a small quantity has been produced in recent years. In Western Australia deposits of flake graphite have been prospected in the Plantagenet district,[9] and at Munglinup, Eucla division, near the south

coast, west of Esperance.[1] Samples from prospect shafts indicate a tenor in recoverable flake of 10 to 37 per cent. Other deposits of flake graphite deposits occur in the Kendenup district, Southwest division,[2] close to the line of the Great Southern Railway, 290 miles from Perth and 50 miles from Albany, the nearest shipping point. The graphite occurs in graphitic schist, and samples taken show a graphite content of 6 to 54 per cent, with picked samples carrying as much as 80 per cent. The flakes, however, are very small, mostly less than 0.5 millimeter in diameter.

Graphite deposits are said to occur in the interior of New Guinea.[3]

LITERATURE.

The following are the most important papers on graphite which have come to the attention of the writer since the issue of the last report.

1. Alling, H. L., The Adirondack graphite deposits: New York State Mus. Bull. 199, Albany, 1918.
   The descriptive portion of this paper has been summarized on page 237. In addition to the excellent description of the New York deposits the report contains much of general interest. The method of microscopic analysis developed by the writer is especially valuable. The microscopic analyses check surprisingly well with the chemical analyses where both are given and yield information as to the type of gangue minerals which is of great value to the miner and which is not shown by the chemical analysis.
2. Bleininger, A. V., Notes on the crucible situation: Metal Industry, vol. 16, pp. 15–16, January, 1918.
   The article contains a short discussion of the adaptability of graphite of different types to crucible manufacture and a detailed study of the properties of crucible clays.
3. Dub, G. D., Preparation of crucible graphite: Bur. Mines War Min. Inv. Ser. 3, December, 1918.
   This paper is one of the most valuable contributions to the subject of graphite technology. A detailed review of mining conditions in Alabama, New York, Pennsylvania, and Texas is given. The various concentration processes are described in detail. The different methods in use are illustrated by flow sheets of typical mills and numerous sketches, and their efficiency is compared. Chemical and mechanical analyses of the finished products are given, and the author makes valuable recommendations for a standard grade of No. 1 flake and improved methods of sampling.
4. Gillett, H. W., and Rhoads, A. E., Melting brass in a rocking electric furnace: Bur. Mines Bull. 171, 1918.
   Does not deal directly with graphite but gives a comparison of costs between the electric furnace used and a coke-fired crucible furnace and shows that under war conditions a huge saving is possible by electric melting.
5. Horwood, C. B., The gold deposits of the Rand, London, 1917.
   Chapter IV contains a discussion of the origin of graphite.
6. Leighou, R. B., Chemistry of materials of the machine and building industries, New York, 1917.
   Contains notes on the use of graphite in foundry facings, paints, and lubricants.
7. Lyon, D. A., and Keeney, R. M., Electric furnaces for making iron and steel: Bur. Mines Bull. 67, 1914.
   Does not deal directly with graphite but describes electric-furnace practice. "Any product that can be made by the crucible furnace can be made by the electric furnace and in most cases with cheaper raw materials and at a lower cost."

8. Miller, B. L., Graphite: Mineral Industry, 1917 (vol. 26), pp. 302–312, 1918.
A short review of the domestic and foreign graphite industry during 1917, with tables of production and imports.

9. Moses, F. G., Refining Alabama flake graphite for crucible use: Bur. Mines War Min. Inv. Ser. 8, December, 1918.
Results of experiments in raising low-grade concentrates to a flake of 90 per cent grade. Tests were made with an aspirator, pneumatic jig, pebble mill, electrostatic separator, oil flotation, and burr mill. The processes recommended are a dry process, consisting of treatment in the electrostatic separator followed by grinding in the burr mill and screening, and a wet process, involving crushing in the pebble mill, concentration by oil flotation, drying, and final grinding in the burr mill, followed by screening. The burr mill was found to be a necessity in the finishing process, where a 90 per cent product was required.

10. Newland, D. H., The mining and quarry industry of New York State: New York State Mus. Bull. 196, 1918.
Graphite, pp. 259–262. Contains description of the mine of the Joseph Dixon Crucible Co. at Graphite, the mines of the Graphite Products Corporation near Saratoga Springs, and the Hooper Brothers' mines near Whitehall.

11. Prouty, W. P., Alabama graphite in 1918: Eng. and Min. Jour., vol. 107, No. 4, pp. 194–195, 1919.
Gives a summary of recent changes in milling practice and the price schedule adopted by the Graphite Producers Association in the autumn of 1918.

12. Searle, A. B., Refractory materials, their manufacture and uses, London, 1917.
Contains notes on the use of graphite in the manufacture of crucibles, fire bricks, and other refractory products.

13. Spearman, Charles, The graphite industry: Canadian Min. Jour., vol. 40, pp. 87–88, Feb. 12, 1919.
Proposes the following flake standards: No. 1 flake should all be above 90-mesh in size, and over half should rest on a 50-mesh screen, and it should contain 85 to 90 per cent graphitic carbon; No. 2 flake should pass through 90-mesh and rest on 120-mesh standard screen. States that experiments showed that 100 grams of Alabama flake, shaken down, occupies 150 cubic centimeters, and the same weight of Canadian flake, 135 cubic centimeters, while 100 grains of Ceylon graphite occupies only 91 cubic centimeters.

14. Toronto University, Department of Mining Engineering, Preliminary report of an investigation into the concentration of graphite from some Ontario ores: Canadian Min. Jour., vol. 40, pp. 189–197, 1919.
A series of experiments is described and the following system is outlined: (1) Crush wet in a rod or ball mill, using an excess of water and the minimum of crushing compatible with the liberation of the maximum of coarse flake; (2) Remove the large flake by oversize screening; (3) Divide the sands into several grades by hindered settling classification; (4) Float each grade separately and by stages, regulating the quantity of oil to the requirements of each stage, making concentrates, middlings, and waste; (5) Regrind the concentrates and middlings separately in a rod mill with excess of water; (6) Screen wet, making a high-grade flake and a dirty undersize to be returned for flotation.
The advantages claimed over the older processes are these: (1) The whole process is wet, eliminating the dust nuisance and avoiding the necessity of drying large quantities of rock; (2) the minimum destruction of flake, owing to its rapid removal, and the minimum of crushing required combine to produce a maximum of coarse flake; (3) separation of the sands into grades renders possible the saving of some high-carbon flake that may not require regrinding, and the sizing of the material helps the separation of graphite and mica in the subsequent flotation; (4) the final product is a flake which is thicker, has a larger proportion of the coarser sizes, and is more brilliant in appearance than flake that is finished by a dry grinding process; (5) the process is simple and does not call for an elaborate flow sheet.

15. Wilson, M. E., Graphite in Port Elmsley district, Lanark County, Ontario: Canada Geol. Survey Summary Report, 1917, pt. E., pp. 29–42, 1918.
Consists chiefly of a geologic description of the Globe mine. The workable graphite ore occurs on the crest of an anticline, in silicified limestone, associated with intrusive pegmatite. This position of the graphite ore and its association with the completely silicified limestone are evidences that the original source of the graphite was the carbonate of the limestone, dissociated by the intrusive pegmatite.

SLATE.

By G. F. Loughlin and A. T. Coons.

PRODUCTION.

GENERAL STATISTICS.

The value of the slate sold by the slate quarrymen of the United States in 1918 was $4,038,770. This shows a decrease of 30 per cent ($1,711,196) from the value for 1917. The total values for these two years can not reasonably be compared, as the figures for 1918 do not include a considerable value of output for slate granules for patent roofing, which was used in large quantities in the construction of the Government and other buildings necessitated by the war. Figures of slate granule production in 1918 are withheld so as not to disclose confidential information. The only slate product that showed increase in value in 1918 was mill stock, although the quantity sold showed a decrease.

[a] Includes, in 1917, 4,378,490 school slates, valued at $48,828, and 2,650,563 square feet of blackboard material, valued at $413,163; in 1918, 1,244,740 school slates, valued at $17,016, 1,607,849 square feet of blackboard material, valued at $264,921, and 89,074 square feet of billiard-table material, valued at $33,502, and excludes value of slate granules in 1918.

[b] Value for 1918 is exclusive of value of slate granules.

ROOFING SLATE.

Roofing slate, with a decrease in quantity of 46 per cent, continued the decline, which has been continuous since 1912 and general since 1902, as shown in the accompanying diagram.

The quantity sold in 1918, 379,817 squares, was the smallest ever recorded by the Survey. These figures represent sales made by quarrymen. Besides this, however, more than 20,000 squares of roofing slate was sold in 1918 by firms that make a practice of buying and storing the output of small quarries and later placing the product on the market as demand requires. This output was accounted for in the published figures of sales for previous years.

The value of roofing slate, after a slight gain of 0.08 per cent in 1917, showed a decrease of 35 per cent ($1,192,609). The total value for 1918 was $2,219,131 and was the lowest reported since 1888. The average price per square, which until 1914 had never exceeded $4, was $5.84 in 1918, 99 cents more than in 1917.

The producers of roofing slate report that 1918 was the most unsatisfactory year they ever experienced. Many of the quarries were idle and most of those in operation were worked only part time. The nearness of the slate quarries to shipyards and munition plants made labor scarce and costly. Operating expenses were reported as increasing from 25 to 100 per cent. Coal was hard to obtain and some quarries remained closed on that account. Advances in price ranged from 50 cents to $1 a square, and it was stated that although the increase in price did not fully meet the increased cost of operating, the quarrymen continued operations to retain such labor as they had and to keep the quarries in good condition. In one section of Pennsylvania the demand for roofing slate was reported as normal, but in most regions the embargoes on permanent building operations, as well as local conditions, reacted against the industry.

The prices quoted for Pennsylvania slate f. o. b. quarries on January 1, 1919, ranged from $10 to $19 per square (subject to discount for prompt payment) according to size and quality of the slates. This shows a very large increase in price over the average value of $5.50 per square for the slate sold in this State in 1918.

An attempt at organization for the better handling of the output of roofing slate of several quarries in the Bangor district was made in 1917. Conditions prevailing in 1918 and the first months of 1919 have presented many difficulties for this work, and there has been only a little advertising through the trade papers thus far. It appears, however, that the present time, which marks the beginning of renewed building activity, affords a great opportunity for the presentation to the general public, and especially to architects, contractors, and construction engineers, of the undoubted merits of slate as a roofing material.

Roofing slate, according to some producers, was not given due recognition in the construction of houses for war workers and other war structures, owing to erroneous ideas regarding the weathering qualities of slate. One only needs to examine buildings with slate roofs from 50 to 75 years old in this country and from a century to more than two centuries old in Europe to become convinced that standard slate has demonstrated satisfactorily its weathering qualities over a much longer period than any other roofing material.

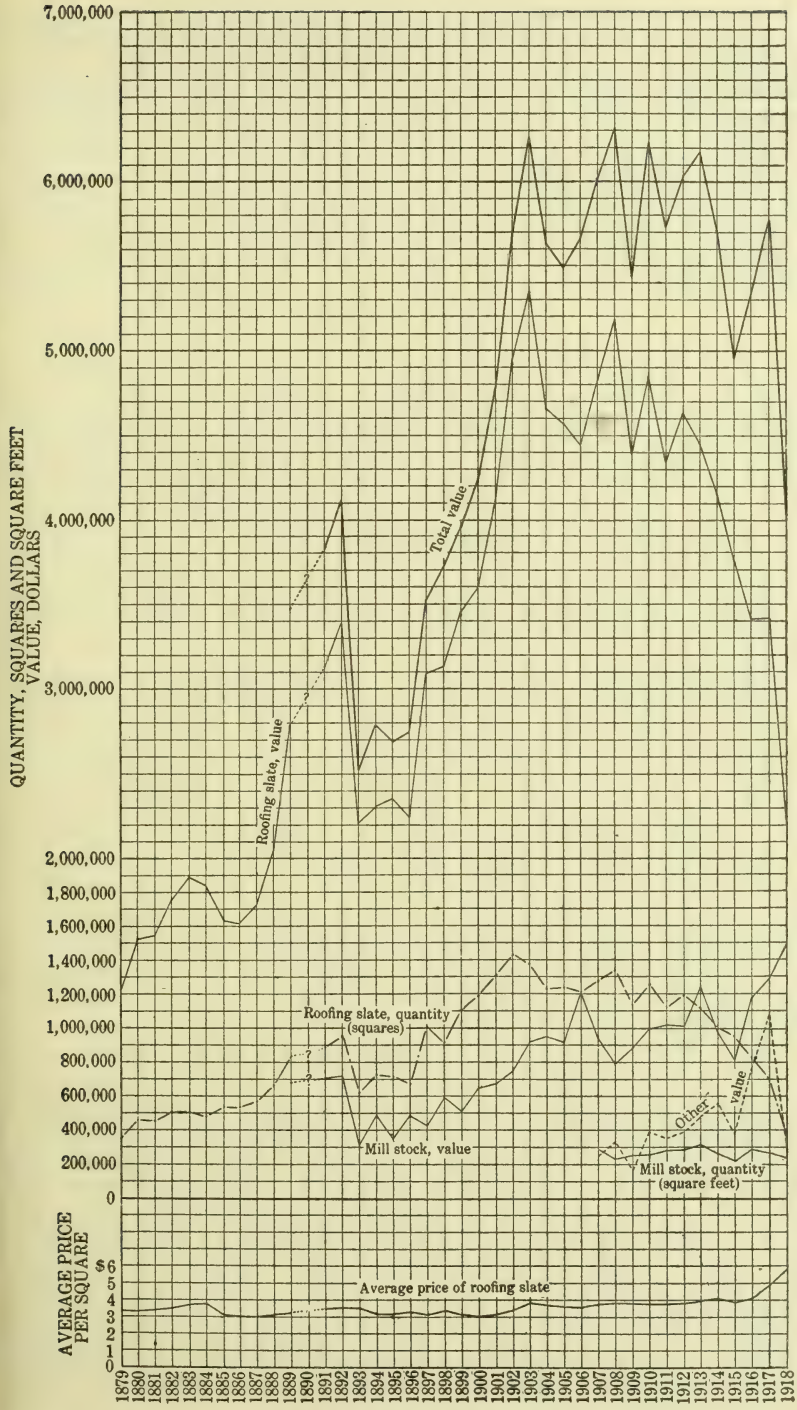

FIGURE 56.—Diagram showing production of slate in the United States from 1879 to 1918, inclusive. Number of square feet of mill stock is divided by 20 to show proper relation to roofing slate. The value of "other" slate in 1918 does not include that of slate granules.

Small sizes of roofing slate embedded in asphalt as material for flat roofs have been utilized for several years by the Inlaid Slate Co., of Bangor, Pa. In 1918 in order to overcome the problem of replacing the metal flashings used on slate roofs by some material equally convenient, more lasting, and less needed as a war material, this company developed a substitute.[1] "Waste" pieces of slate, 3 by 6 inches, washed and heated to 200° F., were applied to three-ply standard Government roll roofing, which was backed by burlap and an asphaltic mixture guaranteed not to melt at less than 400° F. This material is cut in strips of usual width and adjustment at any angle provided for.

MILL STOCK.

Mill stock for slate for structural, sanitary, and electrical use, which had shown a gain in quantity of 26 per cent in 1916 and a decrease of 5 per cent in 1917, showed a further decrease of nearly 12 per cent in 1918, and was the smallest quantity reported as sold, except in 1908 and 1915, since record of quantity has been kept by the Survey. The value, however, which had steadily increased up to 1913 and underwent a decided slump in both 1914 and 1915, has steadily increased since and in 1918 was the highest ever recorded ($1,498,164). The average price per square foot was 31 cents in 1918, an increase of 8 cents in 1918, and following an increase of 3 cents in 1917.

In previous years the statistics of mill stock have been compiled according to the sale of the material as rough blocks or in a finished or partly finished state. In 1918, however, in order to have a better grasp on the uses of slate, the quantity of slate sold for electrical purposes was separated from that sold for structural and sanitary uses, so that a comparison of figures for the two years according to uses is not possible. The structural and sanitary slate sold in 1918 amounted to 3,129,194 square feet, valued at $756,952, or 24 cents a square foot. The electrical slate sold in 1918 amounted to 1,711,939 square feet, valued at $741,212, or 43 cents a square foot. The producers of mill stock reported the same difficulties with labor and cost of operation as the manufacturers of roofing slate. Although the price was reported as having advanced 25 per cent with fair demand, many quarries were idle.

Nearly 90 per cent of the structural and sanitary slate was produced in Pennsylvania and the remainder in Vermont. The greater part of the electrical slate was from Vermont, although Maine and Pennsylvania furnished considerable quantities. The production of slate for blackboards and bulletin boards, which represented about 7 per cent of the total value in 1917 and a little more than 6 per cent in 1918, decreased 39 per cent in quantity and 36 per cent in value in 1918. The curtailment of the building of schoolhouses was given as the reason for this decrease. The average price was practically the same in 1918 as in 1917—16 cents—although many operators reported that there had been an advance of 1 cent a square foot in price in 1918. The exports of this kind of slate also decreased considerably in 1918. The greater part of the blackboard material

[1] Stone, November, 1918, pp. 510–511.

is furnished by Pennsylvania, but in 1918 some blackboard slate was reported from Vermont.

School slates showed an even greater decrease than blackboards—72 per cent in quantity and 65 per cent in value. All the school slates reported were from Pennsylvania. The exports of these slates increased about 27 per cent in quantity. The average price was $11.15 per thousand in 1917 and $13.67 per thousand in 1918.

Slate sold for billiard tables in 1918 amounted to 89,074 square feet, valued at $33,502, a decrease of 53 per cent in quantity and of 45 per cent in value. The average value was 32 cents a square foot in 1917 and 38 cents in 1918. The amount of slate exported for this use decreased over 34 per cent.

OTHER USES.

Slate reported for other uses included small quantities sold for tombstones, for use on roads, and as slabs for various purposes. Slate granules included under this heading in 1917 are excluded in 1918 so as not to disclose individual production.

COLORED SLATES.

Several of the companies in the New York-Vermont colored-slate belt report sales of two or more colors of slate and do not separate their product according to colors, but enough of them report regularly for the same color each year to afford the comparison furnished by the following figures:

Colored slates sold in New York and Vermont in 1909 and 1914–1918.

Year.	Red.	Green.			Purple.	Purple and green, mottled, variegated.	Total.
		Sea-green.	Unfading green.	Green.			
1909	$37,789	$758,372	$183,135	$246,612	$145,041	$443,430	$1,814,379
1914	36,256	789,055	81,884	190,265	121,935	307,628	1,527,023
1915	28,223	672,917	71,765	191,573	88,987	303,199	1,356,664
1916	16,039	529,875	51,328	122,487	265,523	328,154	1,313,406
1917	[a] 18,796	350,762	77,805	232,469	216,454	474,055	1,370,341
1918	[a] 11,383	343,309	42,574	237,182	175,656	430,709	1,240,813

[a] Value of 1,719 squares of roofing slate in 1917 and of 852 squares in 1918.

The decrease in 1918 in the total value of colored slates sold was 9.5 per cent and followed an increase of 4 per cent in 1917. The greatest decrease shown was for "unfading green" slate (45 per cent). Red slate decreased 39 per cent in value, but the quantity, 852 squares for roofing, decreased 50 per cent. All the "sea-green" slate reported was sold for roofing and amounted to 61,060 squares, valued at $343,309, a decrease of only 2 per cent in value. The "green" slate reported sold was 39,225 squares for roofing, valued at $237,182, an increase of 2 per cent in value. The "unfading green" slate was sold for roofing slate and as mill stock for structural, electrical, and billiard table use. The miscellaneous colored slates included 13,967 squares, valued at $99,965, and reported as

"unfading green" and "mottled" slate. All the purple slate reported was mill stock and amounted to 541,822 square feet, valued at $175,656, a decrease of 19 per cent in value. This slate was sold chiefly for electrical use (477,422 square feet), but some was sold for billiard tables, blackboards, and structural slate. The slate included under the miscellaneous varieties is both roofing slate and mill stock and decreased 9 per cent in value in 1918.

SLATE INDUSTRY BY STATES.

Slate deposits in Arizona, Arkansas, California, Colorado, Georgia, New Jersey, and Tennessee were inactive in 1918, but sales were made from stock on hand in California, New Jersey, and Tennessee. It was reported to the Survey that the slate quarry near Placerville, Eldorado County, Calif., might be reopened in 1919. The slate granules annually reported from Utah have been omitted for 1918, in order to exclude this entire product, as explained on page 267.

d Includes California, Maine, New Jersey, and Tennessee.

MAINE.

Except a small quantity of roofing slate and slate for tombstones, all the slate quarried in Maine was for electrical uses. The value of the total output in 1918 decreased 11 per cent. Labor conditions were very unsatisfactory, as it was difficult for the quarryman to maintain an adequate working force in competiton with the attractive wages offered by the shipyards on the Maine coast. Prices were reported as higher than in previous years but not high enough to meet the increased expense of operation.

MARYLAND.

Maryland slate finds its use chiefly for roofing, and besides the lack of demand for this use the quarries were hampered by loss of labor to the shipyards and ammuniton plants.

NEW YORK.

In New York the slate sold was red slate for roofing—852 squares, valued at $11,383; the price per square ranged from $11.50 to $16. A considerable quantity of slate ground into granules for the manufacture of patent roofing is not included.

PENNSYLVANIA.

The value of the slate sold by the quarrymen in Pennsylvania in 1918 ($2,304,647) was less than in any year since 1896. The decrease in value in 1918 amounted to $1,002,057 (30 per cent) and followed increases of 6 per cent in 1917 and 3 per cent in 1916. Although a portion of the Pennsylvania slate (7 per cent of the total value) was sold for electrical uses and therefore came under the head of an essential commodity, the remainder was practically all furnished to the building industry and was therefore severely affected by the embargoes incidental to all structural materials. These embargoes included regular roofing slate, structural and sanitary slate used in interior building and blackboard and bulletin boards. Lack of transportation doubtless accounted for the decreased export trade in blackboards, school slates, and slate pencils. Pennsylvania, however, continued to rank first among the slate-producing States with 57 per cent of the total value of the output in 1918, practically the same as in 1917.

Roofing slate decreased 54 per cent in quantity and 45 per cent in value in 1918. In 1917 there was a decrease of 14 per cent in quantity, with an increase of 3 per cent in value. In 1917 the average price per square increased 74 cents; in 1918 it increased 89 cents, with the prospect of further increase for 1919. In 1917 Pennsylvania slate represented 65 per cent of the total quantity and nearly 62 per cent of the total value of all roofing slate sold in the country. In 1918 these figures were 56 per cent of total quantity and 52 per cent for total value. This percentage of total production lost by Pennsylvania in 1918 was gained by Vermont.

In 1917 the figures for mill stock reported by Pennsylvania included some slate for electrical use. In 1918 the slate sold for elec-

trical use was separated from that sold for structural and sanitary use and amounted to 406,514 square feet, valued at $171,880. If this is included with mill stock for structural and sanitary use, for comparison, mill stock decreased about 19 per cent in quantity but increased 21 per cent in value. The average price in 1918 was 27 cents per square foot—9 cents more than in 1917.

Slate blackboards, including bulletin boards, reported as sold in Pennsylvania in 1918, decreased 40 per cent in quantity and 37 per cent in value. There was an increase of less than 1 cent per square foot in the average price. Slate sold for school slates decreased 72 per cent in quantity and 65 per cent in value in 1918. Slate reported sold for billiard tables decreased 82 per cent in quantity and 84 per cent in value.

About 88 per cent of the total value of slate sold in Pennsylvania in 1918, as shown in the following table, was produced in Northampton County compared with 86 per cent in 1917. The remainder was quarried in Lehigh County. All the quarries in York County were idle.

Slate sold in Pennsylvania in 1917 and 1918.

a In 1917 includes 84,966 square feet of billiard table material, valued at $20,527; in 1918, 14,916 square feet of billiard table material, valued at $3,252.

The number of firms reporting sales in Pennsylvania in 1918 was 49—23 less than in 1917. Several reported sales from stock with quarries closed. The greater number of quarries operated only part time.

The operators commenting on the condition of the slate industry in 1918 all complained of labor conditions, that increase in prices did not cover increased cost of operations, and of decreased demand on account of ban on commercial building. Development work to prepare for an expected increase in business in 1919 was reported by one firm, and another company reported taking up work that did not pay in order to keep the quarries in good condition. The soft vein slate was reported as being especially hard hit and but few quarries were in operation. This slate, on acccount of its well-developed cleavage, softness, and comparatively dull luster, is in especial demand for blackboards and school slates. In the last two years three companies have been formed in Pennsylvania to act as selling agents for different classes of Pennsylvania slate. The Vendor Slate Co. buys the roofing-slate output of several quarries and markets it, the Natural Slate Blackboard Co. acts as selling agent for the blackboard material produced by several firms, and the Structural Slate Co. controls the output of electrical, structural, and sanitary slate. It is hoped by means of these central selling agencies to reduce the cost of marketing slate, to give more publicity to slate products, and to aid the industry by the cooperation of the quarrymen.

VERMONT.

Vermont, which ranks next to Pennsylvania in the production of slate, showed an apparent decrease in 1918 of $578,320 (31 per cent) in the total value of sales reported. The figures for 1918, however, do not include the sales of slate granules used in the manufacture of patent roofing, and an exact comparison of total value for the years 1917 and 1918 can not be made. Nearly 68 per cent of the value of Vermont slate represented in this report was for roofing slate in 1918, and this product decreased 28 per cent in quantity and 16 per cent in value. In 1917 Vermont produced 28 per cent of the quantity of roofing slate sold and in 1918, 38 per cent. The average price per square was $6, 88 cents more than in 1917.

In 1918 millstock amounting to 869,254 square feet, valued at $309,273, was sold for electrical uses. Including this with structural and sanitary slate, as in 1917, the total millstock output increased 25 per cent in quantity and 35 per cent in value. The average price per square foot was 30 cents in 1917 and 32 cents in 1918. Vermont for the first time reported sales of slate for blackboards and billiard tables.

Little comment on the conditions of the industry was made by the Vermont quarrymen. Business was dull, owing to war and labor conditions.

VIRGINIA.

Virginia's slate industry showed a decrease of 10,407 squares (40 per cent) in quantity and of $25,657 (19 per cent) in value in 1918.

The average price per square increased from $5.21 in 1917 to $7.01 in 1918. Only four quarries were in operation. The others were closed on account of labor conditions, but with the expressed design of reopening as soon as conditions became normal.

EXPORTS.

ROOFING SLATE.

The value of the exports of roofing slate in 1918 was $65,224, more than twice as much as in 1917. As no record of quantity is kept for exports of slate and as prices rose so much higher in 1918 than in 1917, it is difficult to determine whether or not the quantity showed any large increase.

Roofing slate exported from the United States, 1913–1918.

1913	$226,413	1915	$46,137	1917	$27,113
1914	139,125	1916	27,630	1918	65,224

The following table was furnished by the Bureau of Foreign and Domestic Commerce, United States Department of Commerce:

Roofing slate exported from the United States, 1917 and 1918.

1917.

Canada	$19,245	West Indies—Continued.	
Mexico	93	Trinidad and Tobago	$111
Central America:		Other British West Indies	1,446
Guatemala	14	Virgin Islands	103

Brazil	70	France	75
Colombia	40	Australia	2,450
British Guiana	5	British South Africa	19
Venezuela	136		27,113
West Indies:			
Barbados	17		
Jamaica	23		

1918.

Canada	$54,478	Hongkong	$94
Mexico	50	Philippine Islands	673
Panama	20	Dutch East Indies	49
South America:		French Oceania	1
British Guiana	290	Australia	4,371
Peru	220		65,224
Chile	4,000		
West Indies:			
Haiti	150		
Trinidad and Tobago	828		

Canada, as usual, was the largest consumer, taking 83 per cent of the slate exported. The greater part of the shipments to Canada were in the later part of 1918. It is possible that some of the roofing material manufactured from slate granules may be included in these exports, as it is known that slate granules were shipped to Canada.

The total imports of slate into Canada shown below are of interest in comparison with exports from the United States to Canada in 1916 and 1917, figures for 1918 not being available.

Slate imported into Canada in 1916 and 1917.[a]

	1916	1917
Roofing slate	[b] $21,335	$20,785
School writing slate	35,887	40,603
Slate pencils	11,309	8,717
Slate of all kinds and manufactures of	28,245	36,788
	96,776	106,893

[a] McLeish, John, Preliminary report of the mineral production of Canada during the calendar year 1917, Canada Dept. Mines.
[b] Represents 4,412 squares.

Altogether slate valued at $83,783 was exported from the United States to Canada in 1918, compared with $51,941 in 1917. The value of other slate than roofing is shown in the next tables. Canada's production of roofing slate in 1917 was 1,422 squares, valued at $7,789,[1] and in 1918, 933 squares, valued at $5,124.

OTHER SLATE.

The following figures of exports of slate for other purposes than roofing were compiled from information furnished directly to the United States Geological Survey by producers and manufacturers. The only increase in quantity shown was in slate for electrical use (28 per cent), the other uses all showed decided decrease. The total value decreased 8 per cent. Electrical slate exported increased nearly 70 per cent in value. Billiard-table slate showed a slight increase in value of exports, as did also slate for pencils. The other products decreased. In 1917 South America received the greatest value of exported slate; in 1918 Asia was first (fourth in 1917), South America was second, and Canada was third (second in 1917). In Asia, China took more than one-half of the output chiefly in the form of slate pencils.

[1] McLeish, John. Preliminary report of the mineral production of Canada during the calendar year 1918, Canada Dept. Mines.

Slate, other than roofing, exported in 1917 and 1918.

[a] Cases weigh from 130 to 165 pounds each; average is 135 pounds.

IMPORTS.

Imports of slate for consumption in the United States have continued to decrease until they are practically negligible. The total values for the last four years have been $2,768 in 1915, $2,200 in 1916, $1,024 in 1917, and $321 in 1918. No sources of these imports are stated.

GYPSUM.

By R. W. Stone.[1]

PRODUCTION.

Nearly 24 per cent less gypsum was mined in the United States in 1918 than in 1917, owing to a reduction in building operations. The output was less than that in any year since 1909, and the great reduction may be ascribed wholly to the war.

Crude gypsum mined in the United States, 1908–1918, in short tons.

1908	1,721,829	1912	2,500,757	1916	2,757,730
1909	2,252,785	1913	2,599,508	1917	2,696,226
1910	2,379,057	1914	2,476,465	1918	2,057,015
1911	2,323,970	1915	2,447,611		

On the other hand, the total value of the crude and calcined gypsum produced in 1918 surpassed that of any other year. Since the Survey's advance chapter on gypsum in 1917 was published the principal producers of gypsum board, block, and tile have revised their figures showing the quantity and value of gypsum used in those products in 1917. The revised figures are here given, and the reason for the change is discussed on another page. According to the revised figures the increase in 1917 was $3,157,420, or 40 per cent, over the total value in 1916, as compared with an increase of $3,000,000 in the 10 years from 1907 to 1916. The increase in 1918 was $354,402, or 3 per cent, over the total value in 1917.

Total value of crude and calcined gypsum, 1908–1918.

1908	$4,075,824	1912	$6,563,908	1916	$7,959,032
1909	5,906,738	1913	6,774,822	1917	11,116,452
1910	6,523,029	1914	6,895,989	1918	11,470,854
1911	6,462,035	1915	6,596,893		

The increase in total value of product, in spite of a decrease of nearly 24 per cent in total quantity mined, was due to the war, which increased cost of production by raising wages and the cost of all supplies. The increase in total value was not general, however. In Michigan, New York, and Oklahoma the value increased, but in Iowa, Kansas, Ohio, Texas, and Wyoming the value was less than in 1917. In all the principal producing States the quantity mined was less.

[1] The statistical tables in this report are the work of Miss L. M. Jones, statistical clerk, with the exception of those relating to imports and exports, which are compiled from the records of the Bureau of Foreign and Domestic Commerce by J. A. Dorsey.

Status of gypsum industry in principal States in 1918, as compared with 1917.

State.	Decrease in quantity mined (per cent).	Increase or decrease in value (per cent).
Iowa	29	− 5
Kansas	30	−19
Michigan	24	+12
New York	12	+16
Ohio	26	− 5
Oklahoma	20	+13
Texas	39	−16
Wyoming	25	− 1

This table shows that the gypsum industry in New York had little to complain of in comparison with the industry in other States. Doubtless the better business conditions in New York were due to its closer geographic relation to the district in which the greatest amount of building was done and to its better equipment for delivering large quantities of gypsum board and block.

Of the States whose production is not shown separately it is interesting to note that the decrease in the quantity of gypsum mined in Colorado and New Mexico was only 5 to 6 per cent, whereas the decrease in California, Arizona, Nevada, Montana, and South Dakota ranged from 16 to 30 per cent.

Gypsum produced and marketed in the United States, 1917 and 1918.

State.	Number of plants reporting.	Total quantity mined (short tons).	Sold without calcining.				Sold as calcined plaster.		Total value.
			Ground for land plaster.		For Portland cement, paint, and other purposes.		Quantity (short tons).	Value.

[a] A small quantity of paint material included with gypsum sold for Portland cement.
[b] Some calcined gypsum sold to glass factories included with boards, tile, etc.
[c] Some dental plaster included with boards, tile, etc.

The average price per ton of crude gypsum sold for use as retarder in Portland cement increased from $1.65 in 1917 to $2.41 in 1918. New York produced nearly 45 per cent of the gypsum sold for this purpose, as it is the nearest source of supply to the great cement industry in eastern Pennsylvania. Nearly 40 per cent of the gypsum sold for land plaster was produced in Virginia; Iowa ranked second and Nevada third in sales of gypsum used for this purpose. The average price per ton of land plaster rose from $2.74 in 1917 to $3.96 in 1918. Most of the 1,986 tons of crude gypsum sold for "other purposes" is gypsum shipped to manufacturers of gypsum products, and no information is available as to the form in which it is finally placed on the market.

Gypsum wall plaster, plaster of Paris, and Keenes cement increased in average value per ton from $5.79 to $7.22, but both the quantity and the total value of these products were less in 1918 than in 1917.

Keenes cement was formerly made in only two or three States, but in 1918 its manufacture was reported in 12 States by five companies. As one company objects to the publication of the figures separately, the quantity and value of Keenes cement is included with wall plaster. The inclusion of this high-priced material with wall plaster and plaster of Paris does not change the average price per ton for these common plasters more than 1 or 2 cents, because the quantity of Keenes cement produced annually is less than 20,000 tons. Prices for it ranged from $10 to $22 a ton in different States.

In 1916 and 1917 dental plaster was reported as produced in six States, but in 1918 it was reported by only one producer. To avoid revealing confidential information the quantity and value in 1918 have been added in with other material.

More than 60 per cent of the calcined gypsum reported sold to plate-glass factories was produced in Ohio, about one-fourth was produced in Michigan, and the remainder in Iowa. The price increased from $5.25 to $6.26 per ton.

Plaster board, tile, and blocks were reported from 15 States at 28 plants operated by the original producers of the gypsum used in their manufacture, as compared with 19 plants in 12 States in 1917. Plants of firms that do not mine gypsum are not included here because the gypsum used by them is already accounted for in these tables as plaster sold by original manufacturers. Of the 134,979 tons of gypsum made into gypsum boards, block, and tile, New York produced 40,000 tons, Iowa 36,000, and Michigan 33,000.

Large quantities of gypsum board were used by the United States Government in the construction of temporary buildings required for the housing of both military and civilian organizations.

The supervisor of material purchase, housing section, Emergency Fleet Corporation, reported to the Geological Survey February 17, 1919, as follows: "We have used, approximately, 16,000 tons of gypsum plaster and 18,000,000 square feet of gypsum plaster board. We have also used a small quantity of gypsum partition tile, but the amount is negligible."

The manager of the construction division of the United States Housing Corporation stated in a letter to the Geological Survey February 6, 1919, that gypsum roof tile and partition tile were not used in any of the Housing Corporation's buildings, but submitted

the following table showing the quantity of gypsum plaster and board used:

Gypsum products purchased and used by the United States Housing Corporation.

Project.	Gypsum wall board.	Gypsum plaster board.	Gypsum cement plaster.

The chief of the Construction Division of the War Department informed the Geological Survey in a letter dated February 8, 1919, that representative operations where gypsum wall board was used under various conditions and with different treatments were as follows:

Housing, Sun Village, Chester, Pa.; joints filled; papered.
Housing, Bethlehem, No. 24 project, Bethlehem, Pa.; same treatment.
Housing, Fairview project, Camden, N. J.; plaster board plastered with gypsum wall plaster and white coated.
Walter Reed Hospital, Washington, D. C.; joints covered with battens; painted.
General Hospital, Grand Central Palace, New York City; painted.
All Army camps and cantonments—Mills, Knox, Meade, Eustis, Custer, McClellan, etc.; nailed in place; no battens; no paint.
All hospital construction in 1918; painted or not; joints covered or not.
All aviation camps variously located; no battens; painted or not.
War Trade Board, Fuel Administration, and other buildings, Washington, D. C.
Dormitories, Washington, D. C.; plaster boards; joints covered; papered.

The quantity and value of gypsum reported as sold in 1917 for use as boards, tile, and blocks and for other purposes was 142,528 short tons, valued at $417,567, an average price per ton of $2.93. This average price was an increase of 39 per cent over the price in 1916 and was supposed to represent only the gypsum used in the board, tile, and blocks, and not the finished products. It was not clear, however, why the value of calcined gypsum so used should not be as great or greater than that of stucco and wall plasters, or between $5 and $6 a ton. The attention of the producers was called to this seeming discrepancy, and it was found that in some reports received the weight of steel reinforcing or other material used in

gypsum blocks had not been deducted, so that the tonnage reported was too great, and that in some reports the value given had been the cost instead of the selling price of the finished product less cost of reinforcing, filler, paper, etc. The revised figures for 1917 are 131,056 short tons of gypsum sold for boards, tile, blocks, and other purposes, valued at $1,038,676, or an average price per ton of $7.93. In 1918 the quantity of gypsum sold for these purposes was 140,343 tons, valued at $1,665,741, or $11.88 a ton.

BUSINESS NOTES.

The Douglas Gypsum Block & Plaster Co., Douglas, Ariz., beginning in August, 1918, made a small output, mostly in the form of cast building blocks. Gypsite from a deposit 5 miles east of Douglas was used. Operations began with one kettle. In the arid climate of southern Arizona gypsum blocks have been used for many years for exterior as well as interior construction and successfully withstand exposure.

The Centerville Gypsum Co., Centerville, Iowa, was idle because the mine, which is reached by a shaft about 500 feet deep, is flooded.

The plant of the Wasem Plaster Co., Fort Dodge, Iowa, was burned May 16, 1918, and rebuilt later in the year.

The Kelly Plaster Co., Sandusky, Ohio, operated its plant at Castalia only 18 days, closing down January 18, 1918, because of inability to secure service from the railway line connecting with the plant.

The plant of the Southwest Cement Plaster Co., at Okeene, Okla., burned in August, 1918, and was not rebuilt.

The Colorado Portland Cement Co., of Denver, Colo., which has been leasing from the Red Buttes Cement & Plaster Co., at Red Buttes, Wyo., purchased that plant in December, 1918.

The Three Forks Portland Cement Co. mined gypsum at Cavern Spur, Gallatin County, and at Hanover, Fergus County, Mont. Cavern Spur is in the canyon of Gallatin River east of Cardwell, and the gypsum deposit is just below the limestone cave in the Lewis and Clark National Monument.

The Gypsum Industries Association, an organization composed of gypsum producers in the United States and representing 85 per cent of the product, maintains an office at 111 West Monroe Street, Chicago, Ill. The officers of the association are: President, R. C. Haynes, Acme Plaster Co., St. Louis, Mo.; vice president, J. C. Seguine, J. B. King & Co., New York, N. Y.; treasurer, J. A. Henley, American Cement Plaster Co., Chicago, Ill.; secretary, H. H. Macdonald; chief engineer, V. G. Marani; agronomist, Dr. Wm. Crocker.

Late in 1918 the War Service Committee on Gypsum established an office in Washington, D. C., with Virgil G. Marani, C. E., in charge. This committee assisted and cooperated with the building-materials section of the War Industries Board. The committee was prepared to furnish information regarding the uses of gypsum products in conformity with accepted engineering and architectural practice for gypsum plaster for all purposes; plaster board for lathing material; wall board for interior wall finish, suspended ceilings, and partition; furring and inclosure tile; poured monolithic roof construction; and

precast slab roof construction. The committee could also furnish information regarding sources of supply, location of mines and mills, daily output, stocks, prices f. o. b. at mills, and freight rates. The Washington office was discontinued in January, 1919, but the Gypsum Industries Association formed a special service committee with V. G. Marani as secretary to serve until discharged by the War Industries Board.

MINE AND MILL DATA.

There were 68 active gypsum mines, quarries, and pits in the United States and Alaska, which supplied 57 domestic mills in 1918. Two mills sold ground gypsum only, 24 sold only calcined material, and 31 sold both calcined and uncalcined gypsum. Of the 57 mills, 40 used rock gypsum, 11 used gypsite, and the others used both gypsum and gypsite, except 1 plant, which reported the use of selenite crystals.

Practically all the mills are equipped with kettles for calcining. The fuel used was coal at 35 mills, oil at 12 mills, wood at 1 mill, coal and oil at 5 mills, and coke at 2 mills.

Fifteen mills reported the manufacture of Keenes cement and 23 mills reported making gypsum blocks or boards.

Domestic gypsum was calcined in 1918 at plants in the following places:

Arizona: Douglas.
California: Amboy.
Colorado: Loveland, Portland.
Iowa: Fort Dodge.
Kansas: Blue Rapids, Medicine Lodge.
Michigan: Alabaster, Grand Rapids, Grandville.
Montana: Hanover.
Nevada: Arden, Moundhouse.
New Mexico: Acme, Oriental.
New York: Akron, Garbutt, Oakfield.
Ohio: Castalia, Gypsum, Port Clinton.
Oklahoma: Acme, Eldorado, Okeene, Southard.
Oregon: Gypsum.
South Dakota: Black Hawk, Piedmont.
Texas: Acme, Plasterco.
Utah: Nephi, Sigurd.
Virginia: North Holston, Plasterco.
Washington: Tacoma (using Alaska gypsum).
Wyoming: Kane, Laramie, Red Buttes.

IMPORTS.

The decline from an annual importation of more than 400,000 tons prior to 1914 to imports of less than 60,000 tons in 1918 is a measure of the effect of the war on the manufacturers of gypsum products in the United States who generally import their raw material. Gypsum imported into the United States comes almost exclusively from Nova Scotia and New Brunswick. Of 50,653 tons imported crude in 1918, more than 50,000 tons came from Canada, less than 200 tons from England, and a few tons from China. The importation in several different months of 1 ton or less of crude gypsum from Hongkong, entering at Honolulu and San Francisco, is a peculiar fact, for which the writer is curious to find an explanation.

The value of manufactured plaster of Paris imported in 1917 was reported as $5,955. This was in error by the omission of pearl hardening valued at $61. In the following table the correction is made, the value in 1917 being $6,016. The total value of imports in 1918, $129,056, is only about one-ninetieth of the total value of the domestic production.

Gypsum imported and entered for consumption in the United States, 1913–1918.[a]

Year.	Unground.		Ground or calcined.		Value of manufactured plaster of Paris.	Keenes cement.		Total value.
	Quantity (short tons).	Value.	Quantity (short tons).	Value.		Quantity (short tons).	Value.	
1913	447,383	$473,594	4,542	$31,277	$52,051	1,851	$26,185	$583,107
1914	369,214	392,118	3,559	27,931	24,792	1,007	17,511	462,352

[a] Figures compiled from records of the Bureau of Foreign and Domestic Commerce, Department of Commerce.

Imported gypsum from Nova Scotia was calcined in 1918 at New Haven, Conn., at New Brighton and New York City, N. Y., and at Chester, Pa. As the quarries commonly supplying these plants are on the Bay of Fundy, the rock is shipped by boat. Shipments can be made by rail, but this is not customary because of the higher cost. The War Trade Board restricted the importation of gypsum from overseas by licensing, and the United States Shipping Board used the fleet of J. B. King & Co., of New York, the largest importers, for coastwise movement of coal. Licenses were revoked June 11, 1918, except for such gypsum as might be carried on sailing vessels or by barges allocated for that purpose. Consequently imports for the year were very small.

EXPORTS.

The data in the following table were obtained from the Bureau of Foreign and Domestic Commerce, Department of Commerce. The figures for 1917 are for the first half of the year only, as during the second half plaster of Paris and plaster or wall board were included in "All other articles." Figures for plaster or wall board are available for all of 1918 and are given below.

Value of plaster of Paris and plaster or wall board exported, 1916–1918.

Country.	Plaster of Paris.			Plaster or wall board.		
	1916	1917	1918[a]	1916	1917	1918

Egypt				2,998		
	13,076	20,153		108,505	106,118	421,985

Exports of plaster or wall board in 1918 were valued at $421,985, or nearly four times as much as for 1916. Japan alone took material valued at $113,931, or more than the total value of these exports in any previous year. The next largest buyers were Cuba, $81,910; Australia, $70,796, and Canada, $39,785. As the usefulness of gypsum plaster or wall board becomes better known the quantity exported should materially increase.

PRODUCTION OF GYPSUM IN CANADA.[1]

Because of the general cessation of building activities during the war, the production of gypsum fell in 1918 to less than one-quarter of the quantity mined in 1913. The difficulties in obtaining transportation by boat for shipments from the maritime Provinces was a contributory cause of the decreased output. The total quantity of gypsum rock quarried in Canada in 1918 was 155,298 tons, of which 88,748 tons was calcined.

[1] Preliminary report on the mineral production of Canada during the calendar year 1918, Canada Dept. Mines, Mines Branch.

Gypsum produced and marketed in Canada, 1917 and 1918.

Year.	Quantity (short tons).	Value.
1917	336,332	$881,984
1918	152,287	823,006

The shipments of all grades amounted to 152,287 tons, valued at $823,006, and included lump gypsum, 43,728 tons, valued at $47,727; crushed, 25,074 tons, valued at $55,079; fine ground, 4,558 tons, valued at $12,621; and calcined, 78,927 tons, valued at $707,579. By provinces the shipments were: Nova Scotia, 49,365 tons, valued at $115,976; New Brunswick, 27,225 tons, valued at $214,114; Ontario, 38,214 tons, valued at $151,564; Manitoba, 37,483 tons, valued at $341,352.

GYPSUM IN FLORIDA.

Gypsum has been reported at only one locality in Florida, and this locality is not readily accessible, for it is a low-lying area of hummocky land, known as Bear Island, in the midst of a swamp about 6 miles west of Panasoffkee. It was examined by D. T. Day about 20 years ago. At the time of his visit there was a logging road across the swamp, but that road has been torn up, and the place is now less easy to reach. The following description is quoted from Day's report: [1]

In the southern and southwestern portion of this so-called island the gypsum reaches the surface, with no covering whatever except an inch or two of vegetal mold. By striking a hoe into this the gypsum may be dug up in a soft state like clay, but it soon hardens on exposure to dry air. It is greenish while wet and turns white on drying. Where the gypsum is at the surface there are knolls from 10 to 50 feet square and 3 to 6 feet higher than the adjoining land, but the gypsum is found almost everywhere by slight excavation. The deposit is probably gypsite, or secondary gypsum.

Two pits sunk through it have shown it to be 6½ feet thick in one place and 7 feet thick in the other, with the usual light Florida sand underneath. Mixed through it are boulders of very impure limestone, with occasional hard, flinty ones. As a rule the topography of the country will admit of digging 6 or 8 feet through the gypsum without encountering any considerable amount of water, except in the wet season.

The quality of the gypsum is almost uniform in all the places from which specimens were taken. The quantity is evidently sufficient for a large supply. The only difficulty to be anticipated in the mining is the fact that the lumps of limestone would be encountered at irregular intervals; their character makes it evident that they are residual lumps from limestone which has been dissolved by the action of rain water, as in many other parts of the State. It is probable that the floor of the deposit will frequently be a bed of limestone, very irregular in its surface, so that it will be difficult to dig all the gypsum from it by cheap means.

According to a description by Prof. F. H. H. Calhoun, of Clemson College, S. C., there is at this locality a deposit of powdery to granular gypsum evidently formed from springs and of variable composition, varying from pure gypsum to 22½ per cent of calcium carbonate. He describes it as in places from 3 to 7 feet thick with an overburden of 3 feet and elsewhere from 6 to 12 feet thick without overburden. The following quotation is taken from Calhoun's description.[2]

[1] Day, D. T., Gypsum deposits in Florida: U. S. Geol. Survey Bull. 223, p. 48, 1904.
[2] Mineral Industry for 1917, p. 117, 1918.

This deposit is probably the same one visited by Dr. Day, but he evidently did not see the best exposures. The material appears in sec. 23, T. 20, R. 21, as a huge mound from 6 to 10 feet thick. It has an average length of 150 yards and an average width of 60 yards.

North of this large deposit, which occurs on what is known as Soapstone Island, the deposits become thinner and less continuous. It might be best described as a swell or saucer type.

This type continues for some 200 yards and then gradually gives place to the type of deposit described by Dr. Day on Bear Island. The deposits on Bear Island consist of isolated mounds of gypsum from 6 to 100 feet in diameter and probably average 3 or 4 feet in thickness. I estimate that the deposit on Soapstone Island contains about 35,000 tons, the adjacent deposit about 70,000 and that on Bear Island probably as much, but so scattered as to make quarrying difficult. I found very little evidence that these mounds were connected under the surface.

Mr. Harry Houston, of Brooksville, Fla., has examined these deposits and finds that Bear and Soapstone islands are in the E. ½ sec. 23, T. 20 S., R. 21 E., and that the largest continuous deposit is on Soapstone Island, probably in the NE. ¼ SE. ¼ sec. 23. He sunk many holes with a 2-inch auger and found the deposit from 6 to 10 feet thick, with an average of 8 feet. On the north and west of the large deposit there are many more or less detached hummocks of gypsite. He reports one deposit "3 acres wide and 6 acres long with an average thickness of 8 feet," or approximately 231,000 cubic yards, and another "350 yards long and 140 yards wide with an average depth of 8⅓ feet," or approximately 131,800 cubic yards—a total of 362,800 cubic yards or about the same number of tons.

The writer visited this locality in March, 1919, and learned that gypsite occurs on Bear, Soapstone, and Burnt islands in the swamp west of Panasoffkee and also near Inverness. These islands are about 4 miles west of the Seaboard Air Line Railway at a point 3½ miles south of Panasoffkee. Pine land extends within about three-quarters of a mile of the islands, but the remaining distance is swamp grown up with saw grass more than head high, so that access from this direction is difficult. The islands are easily reached by small gasoline launch from Panasoffkee. It takes about three hours to make the trip across Panasoffkee Lake, up Withlacoochee River and Jumpers Lake, and thence by pole boat up Bear Island Creek to the islands.

The deposits are a soft, incoherent mass of fine gypsum crystals or particles having the character of gypsite. On Bear Island there are many hummocks of gypsite from 3 to 6 feet high, which are said to extend in a northeast direction for nearly a mile in a belt a quarter of a mile wide. According to these estimates, this would be approximately 160 acres, but as the hummocks are detached, with little or no gypsite between them, the available quantity probably is not more than 200,000 tons.

At the south end of Soapstone Island, which is half a mile long, there is an area of several acres in which gypsite forms a comparatively level-topped deposit rising about 10 feet above water level. Bordering it on the west and north are several acres of gypsite hummocks rising to 10 feet in height. The deposit at the south end of Soapstone Island is the largest compact body that has been discovered. Drill holes sunk in it by Harry Houston, of Brooksville, Fla., are reported by him to show an average thickness of 8 feet of

gypsite. Several holes showed 7½ to 9½ feet of gypsite, and two holes 14 and 15 feet deep did not reach the bottom of the deposit.

The overburden consists of 2 or 3 inches of vegetable mold. There is over the whole area a forest cover of palmetto, cabbage palm, cypress, live oak, and other trees, with almost no underbrush. Overturned trees show a flat mass of roots but no tap roots. The bottom of the gypsite deposit seems to be practically at the level of the surrounding swamp, and the gypsite is probably always damp. It might not be difficult to strip off the forest and leave a clean surface of gypsite, but as the highest estimate of available tonnage is only about 360,000 tons a moderate business of 50,000 tons annually would exhaust the deposit in six or seven years. A conservative estimate of 150,000 tons available and a small plant having a capacity of 20,000 tons a year gives the same result—exhaustion in a brief period. Although the deposits could be mined by steam shovel or floating dredge, they have not been developed because of their small size and location in an area of small market, which is easily supplied by gypsum producers in Virginia, and those in the Atlantic Coast States using gypsum from Nova Scotia.

Samples of gypsite were taken by the writer for analysis.

Analyses of gypsite from Florida.

[Chase Palmer, analyst.]

	Bear Island.	Soapstone Island.
Calcium oxide (CaO)	32.39	32.30
Sulphur trioxide (SO_3)	44.10	45.00
Water, loss on ignition, etc.	21.64	21.53
Ferrous oxide (Fe_2O_3)	.52	.32
Silica (SiO_2)	.55	.26

The Bear Island sample was obtained by cleaning off a few inches from the face of an exposure to get unstained material free from vegetation. The Soapstone Island sample was dug 2 feet below the surface in the side of a vertical wall of a hole in the deposit. These analyses are practically identical with that of the sample obtained by Dr. Day.

According to geologic maps of Florida, the area west of Panasoffkee is occupied by rocks of the Vicksburg group, of Oligocene age. This group consists of soft, porous light-gray to white limestone, containing marl beds and layers of chert. The writer did not find limestone exposed near the gypsite deposits but did see nodules of fossiliferous chert between the hummocks of gypsite. The meager evidence suggests, as mentioned by Calhoun, that the gypsite has been derived from springs. It would seem that at some earlier geologic period the land stood at a slightly higher elevation and that gypsiferous waters rising under artesian head reached the surface here and, evaporating, made mounds of gypsite.

According to Mr. S. Stephens, Bushnell, Fla., there is considerable gypsite on Burnt Island, which lies about 200 yards east of the north end of Soapstone Island, and also near Inverness, a few miles north of the Soapstone Island locality. He reports that the deposit near

Inverness is pockety, can be traced about 1½ miles, and does not contain more than 5,000 tons. Of this same deposit Calhoun[1] says:

> Farther north about 5 miles east of Inverness more deposits are found, but in these the type is different. It lies beneath the surface, covered with an overburden from a few inches to several feet in thickness. The deposit itself, I believe, would not average more than 3 feet and is not continuous. This deposit extends south some 2 or 3 miles.

USES.

The uses of gypsum are described in Bureau of Mines Technical Paper 155, "Gypsum products, their preparation and use," by R. W. Stone, 1917,[2] and briefly in Mineral Resources of the United States for 1915 and 1917. In the report for 1917 mention that a patent had been issued for cleaning wool with overburned gypsum was made on information received from a gypsum producer in the Southwest. The use of gypsum for this purpose has not been confirmed.

Several uses not mentioned in these reports have recently come to the writer's attention. Gypsum may be used as an acid reacting material in baking powder. The purchase of considerable quantities of gypsum by large bakeries is not therefore an evidence of food adulteration. Broken pottery molds, a waste product of potteries, are used as a retarder in Portland cement. The old molds are run through a light crusher and used instead of crude gypsum. This same waste material may be used also as agricultural gypsum.

SAND AND GRAVEL.

By R. W. Stone.

INTRODUCTION.

The task of the Geological Survey in collecting the statistics of the production of sand and gravel in the United States has proved very difficult. The small dealers not infrequently are reluctant to give the quantity and value of their output, and many of the new producers do not realize the purpose of the Survey's work. This reluctance to furnish complete or satisfactory information is often due to the desire of the producer to keep all knowledge of his business from his competitors. He does not realize that the statistics of any particular individual or firm are held in strict confidence by the Survey and are not given out except by his special permission. The small independent producer should use every legitimate effort to foster his own enterprise, especially when he is surrounded by competitors, but it is to his interest that he and his business be known to the Survey, which may be able to turn more business his way.

In all statistical work the completed totals can be no better than the individual reports. If a man or a firm here and there fails to give the figures showing production and value, or makes erroneous statements, the accuracy of the tabulated statistics is to that extent impaired.

The work done by the United States Geological Survey in connection with sand and gravel is not confined to the tabulation and publication of the statistics of production. Information concerning these products is constantly being sought and compiled and is freely given to any inquirer. An engineer in New York may want a grade of sand that is especially fitted for some particular work there or elsewhere and may ask what source of supply is nearest to his project. The Survey promptly puts him in touch with the firm or firms that can best supply him sand in the quantity and of the quality he desires. A builder who is far from any source of gravel known to him and who wants to save both time and freight charges in obtaining his supply of gravel asks the Survey for information; or someone forwards to the Survey a sample of sand to learn its use and value and its possible buyers. The Survey tries to help each inquirer, thus benefiting both the producers and the consumers.

PRODUCTION.

Reports received by the United States Geological Survey from 2,800 producers show that 61,824,426 short tons (of 2,000 pounds) of sand and gravel were produced in 1918. However, the production in 1918 was 14,894,899 tons less than in 1917, when it was 76,419,325 tons. Nevertheless, the average price per ton in 1918 was 61 cents,

or 33 per cent more than the average, 46 cents, received the year before, so that notwithstanding a heavily decreased output the value of the production in 1918 was $37,927,079, as compared with $35,296,932 in 1917, an increase of $2,630,147.

The producers found business better during the first half of the year, but after July 1, 1918, there was a pronounced decline in the volume of business. The date of this change coincides closely with the date when freight rates were increased. General Order No. 28 of the United States Railroad Administration, providing for an increase of 25 per cent on practically all commodities, went into effect June 25, 1918. The freight rates on sand and gravel were increased 1 cent for each 100 pounds, or 20 cents a ton, equal to about $6 or $7 a carload. An increase of this kind might not affect products of the higher grades, but it would and did affect those of the lower grades, which sell at the lowest prices.

For a closer insight into the business of 1918 as compared with that of 1917 the opinions of 634 producers of sand and gravel, representing the six States Michigan, Pennsylvania, New York, Illinois, Indiana, and Ohio, are summarized. Of these, 169, or 27 per cent, reported that their trade was better; 153, or 24 per cent, said that trade was about the same; and 312, or 49 per cent, indicated disappointment. Most dealers in glass and foundry sand were in the first category, and a few producers of paving sand were pleased, but nearly all of these were located where highways were under construction or being improved. Most of the 312 disappointed ones seemed to be producers of building and paving materials.

To meet the exigencies of war the entire output of some sand and gravel concerns was commandeered by the Government, and the operators accepted their fate with the same splendid spirit that was shown by other business men who also wanted to "do their bit" loyally.

The tables which follow have been prepared by Mrs. L. M. Beach who also assisted in the preparation of the text.

Sand and gravel produced in the United States in 1917 and 1918.

IMPORTS.

There was no record of the quantity of sand imported into the United States between January and June, 1918, although the value is said to have been $44,555; but the imports during the last half of the year amounted to 284,036 short tons, valued at $46,910, an average price of 16½ cents a short ton. The total value of the imports was therefore $91,465 in 1918, as compared with $142,586 in 1917.

The word "imported" is somewhat misleading as regards most of the sand covered by these figures, because some of it was carried as ship's ballast and much of it was building sand brought in from Canada to localities near the border. The importation of some special grades of molding sand, such as the French sand for making fine bronze castings and of refractory sands from England for lining certain iron furnaces, is due to the difficulty of making our foreign-born molders and foundrymen believe that the foreign sands with which they are familiar are no better than the American product.

EXPORTS.

No distinct record of the exports of sand and gravel was kept until 1916. In that year the Bureau of Foreign and Domestic Commerce prepared a table showing such exports, which, however, gave value only, not quantity and kind. The exports of sand have been negligible until recently, but there seems to have been a fair gain in 1918 in spite of the shortage of shipping.

The largest quantity of sand and gravel exported was that sent to Canada for use as building material. No information is at hand as to the kinds of sand and gravel sent to the other countries named in the following table:

Value of sand and gravel exported from the United States in 1917–1918.

GLASS SAND.

PRODUCTION.

A total of 2,172,887 short tons of glass sand was produced in the United States in 1918, an increase of 12 per cent over the output in 1917, which was 1,942,675 short tons. The average price in 1918 was $1.94 a ton, an increase of 40 per cent over price in 1917, which was $1.38 a ton. These figures seem especially encouraging to the producers when it is further stated that the total value was

$4,209,728 in 1918, as compared with $2,685,014 in 1917, an increase of $1,524,714, or 57 per cent.

Examination of the accompanying table showing the production of glass sand in the six principal producing States in 1917 and 1918 is interesting. In 1917 Illinois, Pennsylvania, West Virginia, Missouri, New Jersey, and Ohio produced 94 per cent of the entire output of glass sand in the United States, and in 1918 the same States produced 93 per cent. New Jersey had the largest increase in price per ton, 80 cents; Pennsylvania gained 76 cents; West Virginia 73 cents; the inland States—Ohio, Missouri, and Illinois gained 41, 39 and 36 cents, respectively. This difference in increased valuation is mainly attributable to freight differentials, for if the freight charges to a given point differ the producer who has the longer haul must lower his price in order to compete with the dealer who has the shorter haul.

The cost of production varies according to the method used. Most of the glass sand produced in Illinois, for example, is obtained by hydraulic mining; most of that produced in Pennsylvania and West Virginia is quarried and crushed. Pennsylvania, West Virginia, and Ohio, in the order named, have the largest number of glass factories,[1] because they have cheap and abundant natural gas for fuel. The producers of glass sand in Illinois and Missouri must sell their product at a low initial price to compete with producers in the other States named.

[1] The glass industry, report on the cost of production of glass in the United States: U. S. Dept. Commerce Misc. Ser. 60, 430 pp., 1917. Sold by the Superintendent of Documents, Government Printing Office, Washington, D. C., price 35 cents.

GLASS-SAND LOCALITIES.

The resources of the United States in sand suitable for making the more common kinds of glass are very great. Twenty States produced glass sand in 1918, and it occurs in other States in numerous localities.

Localities where glass sand was reported as produced in 1918.

Arkansas: Ruddells.
California: Ione and Lake Majella.
Georgia: Lumber City.
Illinois: Millington, Oregon, and Ottawa.
Indiana: Michigan City.
Iowa: Clayton.
Kentucky: Olive Hill.
Louisiana: Opelousas.
Maryland: Robinson.
Massachusetts: Cheshire.
Missouri: Crystal City, Klondike, Pacific, and Silica.
New Jersey: Cedarville, Millville, Pembryn, South Vineland, and Williamstown Junction.
New York: Cleveland.
Ohio: Austintown, Howard, Massillon, New Lexington, Silica, and Toboso.
Oklahoma: Hickory and Roff.
Pennsylvania: Daguscahonda, Derry, Dunbar, Falls Creek, Kennerdell, Lewistown, Mapleton, Ridgway, St. Marys, Torpedo, and Vineyard.
Tennessee: Lagrange.
Texas: Santa Anna.
Virginia: Mendota.
West Virginia: Berkeley Springs, Buckhannon, Independence, Sturgisson, Terra Alta (Holmes Station), and West Berkeley.

BUILDING SAND.

The output of building sand in 1918 amounted to 19,686,885 short tons, valued at $9,772,556. In 1917 the output was 5,688,102 tons more. In money value the production of 1917 exceeded that of 1918 by $65,132. The decrease in quantity was 22 per cent; the decrease in value was less than 1 per cent.

The Government used a considerable quantity of building sand at numerous army cantonments and also built a large number of more or less temporary offices for its war activities in the city of Washington, as well as large manufacturing plants at other points, in the construction of which large quantities of sand and gravel were used.

In consequence of the restrictions placed upon building for other than Government or war industrial uses, there was a decided decrease in the commercial use of building materials of all kinds. To meet the natural increased demands alone a vast amount of building should have been done in 1918. When normal conditions return the industry will doubtless show great activity.

More building sand was produced in the State of New York in 1918 than any other State, but its total output was very little more than half that of 1917. The output of nearly all the States declined, that of New Jersey alone most closely approaching its output in 1917.

The six leading States in the production of building sand in 1918 were New York, Illinois, New Jersey, Ohio, Pennsylvania, and Indiana, in the order named. These six States produced 50 per cent of the output of the country. There was a general though irregular increase in value, with Pennsylvania in the lead. Pennsylvania received an average of 33 cents a ton more than in 1917, whereas the

price in Ohio advanced only 15 cents and in New York, where the greatest quantity was used, the price advanced only 4 cents.

Building sand produced in six leading States in 1917–18.

MOLDING SAND.

During 1918 the steel mills of the country were busy on war orders and a large number of foundries of metals were working at top speed. For this probably more than for any other reason there was a good demand for molding sand. There was an increase of 5 per cent in the production of sand of this class over that of 1917, and the price per ton received averaged 13 per cent higher. The output was 4,910,178 short tons, valued at $5,121,865, as compared with 4,660,968 tons, valued at $4,303,809, in 1917.

Molding sand produced in the United States, 1910–1918.

Year.	Quantity (short tons).	Value.	Average price per ton.
1910	3,636,167	$2,431,254	$0.67
1911	3,376,717	2,132,469	.63
1912	4,485,380	2,718,726	.61
1913	3,563,583	2,230,217	.63
1914	2,751,209	1,756,383	.64
1915	3,585,746	2,123,203	.59
1916	4,662,649	3,219,839	.69
1917	4,660,968	4,303,809	.92
1918	4,910,178	5,121,865	1.04

The output of six States which produced 85 per cent of all the domestic molding sand dug in 1918 is given in the following table:

Molding sand produced in six leading States in 1917–18.

State.	1917			1918		
	Quantity (short tons).	Value.	Average price per ton.	Quantity (short tons).	Value.	Average price per ton.
Pennsylvania	640,450	$696,734	$1.09	1,158,715	$953,886	$0.82
Illinois	703,208	412,626	.59	885,617	658,205	.74
Ohio	999,974	1,218,217	1.22	857,481	1,493,541	1.74
New York	650,427	808,550	1.24	519,681	770,512	1.48
New Jersey	611,916	651,279	1.06	442,007	626,637	1.42
Indiana	287,483	111,732	.39	298,934	135,605	.45

FILTER SAND.

Filter sand is clean silica sand in sorted sizes, used for beds in water-filtration plants and in small mechanical filters. A city water supply taken from a stream which may be polluted by organic matter or at times heavily charged with sediment is purified by passing it through a sand filter. As silica is insoluble in water, good filter sand, once installed, may be used a long time. In 1918 the output was 51,111 short tons, valued at $74,977, an average price of $1.47 a ton, as compared with 62,170 short tons, valued at $47,351, or 76 cents a ton, in 1917. This was an increase of 58 per cent in value of output and of 93 per cent in average price per ton.

RAILROAD BALLAST.

There was a considerable decrease in the use of sand and gravel for railroad ballast in 1918, although the value increased, in sympathy with prices in general, from 17 to 22 cents a short ton. This material is produced mainly by the users. The railroads that dig out their own ballast are requested by the Survey to give not only the quantity of their output, but its value, based upon market quotations. Certain producing railroads, however, have reported the actual cost of the work of production as the value of the ballast, so that the Survey's estimate of value per short ton of output is more likely to be under than over the market value.

OTHER SANDS.

Sands produced for other uses than those already mentioned are inconsiderable in volume yet are of considerable value, and are tabulated as "Other sands."

The man in the street might regard as a joke the statement that sand is used as an ingredient of some fertilizers; nevertheless, in 1918 New York and Pennsylvania reported that 31,110 short tons of sand, valued at $22,360, was used as filler for fertilizer.

Sand is used as bedding for stock cars. Indiana and Iowa sold 6,339 short tons, valued at $1,602, for this purpose. Shippers of livestock may well compare the cost of other forms of bedding with that of sand at the present average cost of only 25 cents a short ton.

A few tons of fine-grained high-grade silica sand is sold annually for use by blacksmiths in welding iron and soft steel. Sand for this purpose is put up in 25-pound sacks and so brings a high price per ton. Likewise, high-grade silica sand, because of its whiteness, is sold in 3 and 5 pound cartons for use in mechanical toys and thus retails at about $60 a ton.

Producers in New York State chronicle the fact that a considerable quantity of sand known as "grits" found ready sale to poultry raisers.

A few hundred tons of clean, even-grained, and high-grade silica sand from Ottawa, Ill., is sold annually in small individual lots for use as a standard in physical tests of other sands. When a testing laboratory determines the strength of a sand as a component of cement, for example, a test of Ottawa sand is made at the same time under similar conditions for comparison. Such a testing sand must

be procurable with absolute uniformity of physical characteristics through a long period of years. Ottawa sand meets the requirements and is widely used for this purpose.

CALCULATION OF WEIGHTS, MEASURES, AND VALUES.

The unit used in this report for quantities of sand and gravel is the short ton, 2,000 pounds, but many dealers use the cubic yard in their computations and have been so reporting their outputs. Some standard of relation between the two units, however, is necessary, for without such a standard a producer who sells his output by the cubic yard might be getting less for his sand than a competitor who sells by the short ton. Several years ago the Geological Survey asked a large number of producers of sand and gravel to furnish estimates of the average weight of a cubic yard of sand. Some of these dealers made actual tests of the weight of a cubic yard of the sand they sold. The reports show that a cubic yard of sand weighs from 2,000 to 4,000 pounds, the variation being due to differences in mineral composition, moisture content, and packing. The gravels averaged more than the sands, the maximum being 4,200 and the minimum 2,200 pounds. An average of all the weights reported was found, and the result was that a cubic yard of sand is now regarded as weighing 2,665 pounds and a cubic yard of gravel as weighing 2,820 pounds.

In response to repeated requests from new producers as to the method of converting yards to tons a few examples are here worked out. A producer of molding sand, let us assume, got out 500 cubic yards during the year. To find the number of short tons he produced, he should multiply 500 by 2,665, which will give his output in pounds, and should then divide the product—1,332,500—by 2,000 to get the short tons. He would find that he had produced 666¼ short tons.

Possibly this same man sold his sand for $1.35 a cubic yard and is still wondering whether his price equaled that received by his competing neighbor who charged $1.04 a short ton. The competitor received $1.04 for 2,000 pounds of his molding sand. Multiplying 2,665 (the average weight of a cubic yard) by $1.04 and dividing the product by 2,000 gives $1.38½, which is the price the competitor received for an average cubic yard of sand, or 3½ cents more than the man who sold at $1.35 a cubic yard. It happens that $1.04 was the average price per short ton received for molding sand in 1918, and as this is about $1.38½ a cubic yard, some of the readers of this report may discover that they have received more or less than this average through difference in the method they used in selling.

A short method of reducing long tons to short tons is as follows: A long ton contains 2,240 pounds and is therefore 1.12 times as heavy as a short ton. A convenient rule to find the number of short tons is thus to multiply the number of long tons by 1.12.

The quantity of sand in any number of cubic yards may be reduced to weight in short tons by a similar method. It is, however, necessary that the weight in pounds per cubic yard be known. This, of course, varies in different pits. For sand weighing an average of 2,800 pounds a cubic yard, for example, divide 2,800 by 2,000, which

gives 1.4; multiply this quotient by the number of cubic yards, and the product will be the number of short tons. The rule in this case would be: To find the number of short tons divide the weight in pounds of 1 cubic yard by 2,000 and multiply the quotient by the number of cubic yards.

CHATS AND CHERT.

The tables of production given above do not include a considerable quantity of chats or tailings from the Missouri zinc mines. This waste product, which is used on roads, has a nominal value equal to the cost of loading. The shipments of chats in 1918, as reported by the Missouri Bureau of Geology and Mines, amounted to 902,129 short tons, compared with 1,426,716 tons in 1917. Of these shipments in 1917, 1,055,972 tons were from mines in southwestern Missouri and 370,744 tons from mines in southeastern Missouri. More than 1,000,000 tons of this material is believed to have been used for railroad ballast, and the rest for other purposes, such as road metal and concrete.

Neither do the tables include more than 40,000 tons of chert dug in Alabama and valued at more than $17,000.

FLUORSPAR AND CRYOLITE.

By Ernest F. Burchard.[1]

INTRODUCTION.

The period of intense activity in fluorspar mining, which began in 1917, continued unabated until shortly after the signing of the armistice on November 11, 1918. Noteworthy features of the fluorspar industry in 1918 were the continued strong demand, which is reported to have exceeded the supply at times, and the great increase in prices, which were the highest ever recorded. The high prices resulted in the discovery and exploitation of many hitherto unknown fluorspar deposits in the Western States, particularly in New Mexico, Colorado, and Utah. Utah became a shipper for the first time.

DOMESTIC FLUORSPAR MINED AND SHIPPED.

The total quantity of domestic fluorspar reported to the Survey as sold (shipped from mines) in 1918 was 263,817 short tons, valued at $5,465,481, compared with 218,828 tons, valued at $2,287,722, in 1917, an increase in quantity of 44,989 tons, or nearly 21 per cent, and in value of $3,177,759, or 139 per cent. The general average price per ton f. o. b. mines or shipping points for all grades of spar in 1918, according to these figures, was $20.72, compared with $10.45 in 1917, an increase of $10.27 a ton, or 98 per cent. The highest average selling price reported was in Kentucky and the lowest in Colorado. The selling price for much of the Colorado spar, particularly in the Jamestown district, represents the value of uncleaned crude spar at the mines. Before being marketed as a commercial product much of the crude material, including considerable so-called "lump" spar, has to be hauled to custom mills at Jamestown and Boulder and, after milling, the concentrates from the mill at Jamestown require a long haul to the railroad. Therefore prices to the consumer are very much higher than prices at the mines. Average prices in the Illinois-Kentucky district would have been higher had not some companies continued delivering spar on old contracts at prices between $5 and $10 a ton. On the other hand, extreme prices paid for spar for prompt delivery reached $38 to $45 a ton.

As usual, gravel spar, the grade used principally for flux in the manufacture of open-hearth steel, constituted the bulk of the output. The shipments of gravel spar in 1918 amounted to 236,121 short tons, valued at $4,735,260, compared with 183,144 tons, valued at $1,759,920, in 1917, an increase in quantity of 52,977 tons, or 29 per cent, and in total value of $2,975,340, or 169 per cent. The sales of lump

[1] The statistics of domestic fluorspar were compiled by Hubert W. Davis, and those of imports and exports were compiled by J. A. Dorsey, both of the United States Geological Survey.

spar in 1918 were 18,944 short tons, valued at $457,018, compared with 25,548 tons, valued at $349,460, in 1917, a decrease in quantity of 6,604 tons, or 26 per cent, but an increase in value of $107,558, or 31 per cent. Ground spar was marketed in 1918 to the extent of 8,752 short tons, valued at $273,203, compared with 10,136 tons, valued at $178,342, in 1917, a decrease in quantity of 1,384 tons, or 14 per cent, but an increase in value of $94,861, or 53 per cent.

The total quantity of crude fluorspar mined can not be ascertained exactly, because at most of the smaller mines only the cleaned spar is weighed. From such figures as are available, however, it is apparent that the crude spar mined in 1918 amounted to 326,039 short tons, compared with 280,825 tons in 1917, an increase of 16 per cent. The quantity of merchantable spar mined in 1918 amounted to 270,412 short tons.

FLUORSPAR MINED AND SHIPPED, BY STATES.

Fluorspar was mined and shipped in 8 States in 1918—Illinois, Kentucky, Colorado, New Mexico, New Hampshire, Arizona, Utah, and Washington—compared with 5 States in 1917. The Illinois-Kentucky district produced a little more than 83 per cent of the entire output of the United States in 1918. The mines in Illinois produced nearly 60 per cent of the total output of the Kentucky-Illinois district and nearly 50 per cent of the total for the United States. Illinois and New Hampshire were the only States to show decreases in output in 1918. In Illinois this was caused by the flooding of the mines of one of the largest operators and the incompetency of the labor available in the district. Illinois, however, showed an increase in value of output of more than $1,513,000 in 1918, and Kentucky an increase of more than $1,371,000. Crittenden County, in western Kentucky, shipped 75,808 tons of flourspar in 1918, or about 74 per cent more than the shipments from the whole State in 1917. The mines in Livingston and Caldwell counties in western Kentucky and those adjacent to Nicholasville in central Kentucky also showed substantial increases in production. Tennessee has in earlier years produced fluorspar, and deposits are reported to have been discovered in other States, among which are California, Georgia, and Nevada. Small crystals have been observed in the joints of Ordovician limestone near Appleton, Wis. The discovery of a vein of flourspar near Low, Tooele County, Utah, was reported and a small quantity of spar was shipped from it. In Arizona spar was produced in Yavapai, Greenlee, and Pima counties for the first time, the output from this State heretofore having come mainly from the Castle Dome district, Yuma County, from which during recent years there has been little production. There was greatly increased activity in 1918 in the Jamestown district, Colorado, the shipments increasing from 2,326 short tons in 1917 to 22,810 tons in 1918, an increase of 20,484 tons, or 881 per cent. Most of the spar from this district is purchased by local companies that operate concentrating mills, in which the spar is raised in grade before being shipped to consumers. New Mexico, which had not produced any spar since 1915, contributed to the output in 1918.

Such details of the fluorspar shipments by States as may be published by the Survey without revealing statistics of individual producers are given in the following table for the years 1914 to 1918:

Domestic fluorspar sold, 1914–1918.

Washington	1	(a)	(a)
	119	270,412	100.00

[a] Output of Washington included with New Hampshire.

In the following table, summarizing the annual output of domestic fluorspar from 1883 to 1918, the quantities from 1883 to 1905 represent quantity mined; beginning with 1906 they represent quantity shipped from mines. Subnormal conditions are shown in the pre-war year 1914, and more or less abnormal conditions in 1915 to 1918.

Fluorspar produced in the United States, 1883–1918.

Year.	Quantity (short tons.)	Value.	Year.	Quantity (short tons).	Value.	Year.	Quantity (short tons).	Value.
1883	4,000	$20,000	1896	6,500	$52,000	1909	50,742	$291,747
1884	4,000	20,000	1897	5,062	37,159	1910	69,427	430,196
1885	5,000	22,500	1898	7,675	63,050	1911	87,048	611,447
1886	5,000	22,000	1899	15,900	96,650	1912	116,545	769,163
1887	5,000	20,000	1900	18,450	94,500	1913	115,580	736,286
1888	6,000	30,000	1901	19,586	113,803	1914	95,116	570,041
1889	9,500	45,835	1902	48,018	271,832	1915	136,941	764,475
1890	8,250	55,328	1903	42,523	213,617	1916	155,735	922,654
1891	10,044	78,330	1904	36,452	234,755	1917	218,828	2,287,722
1892	12,250	89,000	1905	57,385	362,488	1918	263,817	5,465,481
1893	12,400	84,000	1906	40,796	244,025			
1894	7,500	47,500	1907	49,486	287,342		1,789,341	15,704,924
1895	4,000	24,000	1908	38,785	225,998			

Figure 57 shows graphically the course of the production of fluorspar in the United States from 1883 to 1918, the quantities beginning in 1906 representing shipments from mines. Two periods of fluctuation in output, between 1889 and 1898 and between 1902 and 1908, are in strong contrast with the large and steady increase in production in the periods 1898 to 1902 and 1908 to 1912. The decline from 1912 to 1914, although the greatest in actual tons, is not so great in proportion to the current production as that from 1905 to 1906, and the increase from 1914 to 1918 is clearly the largest in any similar period. For convenience in comparison the imports, beginning with the first full year for which records are available, 1910, are shown on the same diagram.

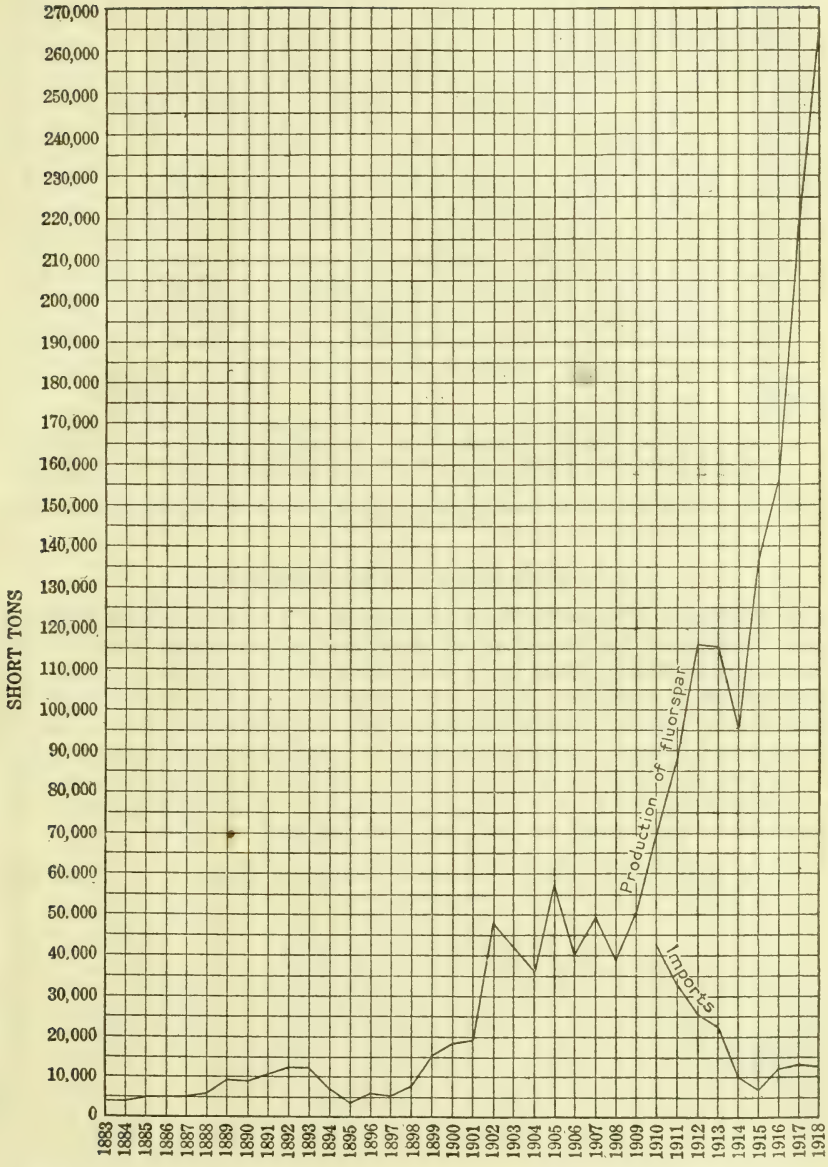

FIGURE 57.—Diagram showing production of fluorspar in the United States, 1883–1918, and imports, 1910–1918.

Figure 58 shows the course of domestic fluorspar prices from 1883 to 1918.

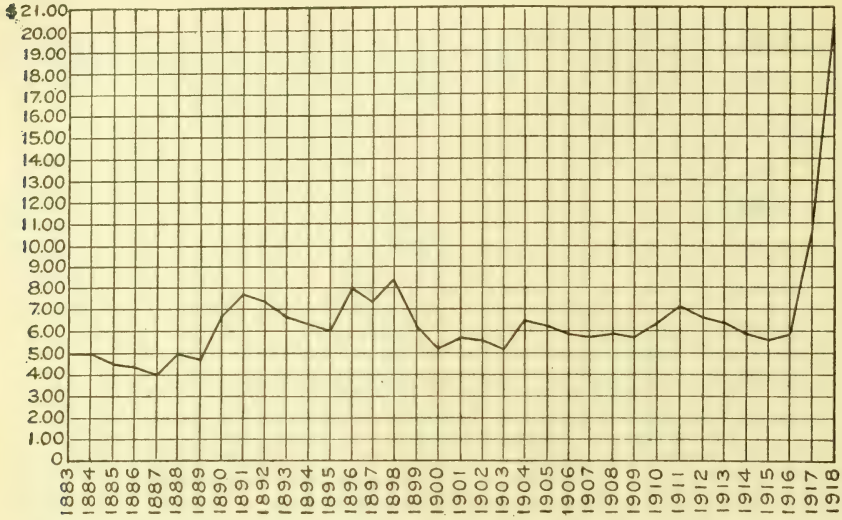

FIGURE 58.—Curve showing average prices per ton of fluorspar at the mines in the United States, 1883–1918.

STOCKS OF FLUORSPAR.

According to the reports of producers the total quantity of fluorspar in stock at the mines or at shipping points at the close of 1918 amounted to 22,779 short tons, compared with 21,655 tons in 1917, an increase of 5 per cent. As the quantity of spar in stock piles is necessarily partly estimated there are variations in the mine reports from year to year which prevent an absolute balance between the quantity mined and the quantity sold and stocks on hand. Data on consumers' stocks are not available, but considerable spar is understood to have been accumulated by the end of 1918.

Stocks of fluorspar at mines or shipping points, by States, in 1917 and 1918, in short tons.

State.	1917	1918

Utah	.....	50
Washington	200	200
	21,655	22,779

IMPORTS.

The imports of fluorspar into the United States entered for consumption in 1918 were 12,572 short tons, valued at $169,364, compared with 13,616 tons, valued at $114,598, in 1917. This represents a decrease in quantity of 1,044 tons, or 7.7 per cent, but an increase in total value of $54,766, or 48 per cent. The value at the foreign

ports of shipment assigned to the imports in 1918 averaged $13.47 a ton, as compared with $8.42 in 1917, an increase of $5.05 a ton, or nearly 60 per cent. The imports of fluorspar in 1918 were equivalent to about 5.3 per cent of the domestic production of gravel spar, as compared with about 7.4 per cent in 1917. According to the values reported, including the duty of $1.50 a ton plus the ocean freight charges, the average cost of imported spar at the docks was $14.97 a ton in 1918, compared with $20.05 for domestic gravel spar at the mine or mills; in 1917 the cost of the imported material, including the duty of $1.50 a ton, was $9.92 a ton plus the ocean freight charges, compared with $9.61 for domestic gravel spar. Ocean freight charges are reported to range from $7.50 a ton, when material is carried as ballast, to $12 a ton otherwise.

The distances that domestic spar must be transported from mines to points where it is consumed are generally much greater than the distances that foreign spar must be carried from the docks to eastern steel plants, so that a slight advantage in price on account of a saving in railway freight charges may be enjoyed by the imported spar at eastern steel plants. Unless ocean freight rates are moderate, however, foreign spar is not in a position to enjoy much advantage in American markets. Foreign spar is not generally of so high grade as the mechanically treated spar from Illinois and Kentucky, and, as fluorspar is of value chiefly according to its purity, purchasers should find that the purer American spar is more efficient and consequently cheaper in the end. During the war difficulties in getting supplies of fluorspar from American mines when needed, on account of freight congestion, lack of cars, difficulties of transportation on Ohio River, and labor troubles, led steel manufacturers to accept readily whatever foreign spar was available. In 1918 England furnished 11,659 short tons, valued at $147,391, or $12.64 a ton at the British port of shipment and Canada supplied 913 short tons, valued at $21,973, or $24.07 a ton.

Fluorspar imported into the United States in 1918.

Source.	Port of entry.	Quantity (short tons).	Value.
England	Massachusetts	273	$3,617

1918	12,572	169,364	13.47

[a] Statistics compiled from records of Bureau of Foreign and Domestic Commerce, Department of Commerce.

CONSUMPTION.

The market for the bulk of the fluorspar sold in the United States depends on the condition of the steel industry, and the demand fluctuates with the rise and fall in the production of basic open-hearth steel. Most of the gravel and some of the lump spar are consumed as flux in basic open-hearth steel furnaces and to a smaller extent in other metallurgic operations. From 1914 to 1918 the sales of gravel spar have constituted between 83 and 90 per cent of the total marketed output of domestic fluorspar. Fluorspar is used also as a flux in iron blast furnaces, iron foundries, and in gold, silver, copper, and lead smelters; in the manufacture of fluorides of iron and manganese for steel fluxing and of sodium fluoride for wood preservation; in the manufacture of glass, enameled and sanitary ware, and of hydrofluoric acid; in the electrolytic refining of antimony and lead; and in the production of aluminum. Other miscellaneous uses of fluorspar that have been reported are as a bonding for constituents of emery wheels, for carbon electrodes, in the extraction of potash from feldspar, and in the recovery of potash in the manufacture of Portland cement.

A close estimate of the annual consumption of fluorspar in the United States can not be made without a knowledge of the stocks maintained by consumers. These stocks are variable, but were probably high at the end of 1918 at the plants of some of the largest consumers, because buying of spar during the year was heavy in anticipation of a possible future shortage, and after the signing of the armistice in Europe some spar not then needed was bought at reduced prices. Moreover, a very small quantity of domestic spar was reported to have been sold between January and May, 1919, although the output of open-hearth steel ingots for the four months January to April, 1919, was about the same as that for the corresponding period in 1918. The sales of domestic spar plus the imports (there are no considerable exports at present, and the figures are not listed separately by the Bureau of Foreign and Domestic Commerce) should give from year to year an index to the quantity entering into consumption and should indicate the relative increase or decrease in consumption. It is credibly reported that the consumption of fluorspar carrying 85 per cent of calcium fluoride averages about 11 pounds to 1 ton of basic open-hearth steel. In 1918 a total of 32,476,571 tons of basic open-hearth steel was manufactured, indi-

cating a consumption of about 178,600 tons of gravel spar. The marketed production of gravel spar was 236,121 tons, thus indicating a surplus of about 57,500 tons in the hands of the consumers at the close of 1918. The total quantity of all grades of spar apparently consumed in 1918 was 276,389 short tons, as compared with 232,444 short tons in 1917, an increase of about 19 per cent.

The general relation between the consumption of fluorspar and the output of open-hearth steel may be noted by comparison of the following two tables:

Fluorspar available for consumption, 1910–1918, in short tons.

	Sales of domestic spar.	Imports for consumption.	Apparent consumption.
1910	69,427	42,488	111,915
1911	87,048	32,764	119,812
1912	116,545	26,176	142,721

FLUORSPAR IN FOREIGN COUNTRIES.

CANADA.[1]

The production of fluorspar in Canada again shows a substantial increase. The principal production from Madoc, Ontario, was supplemented by shipments from a recently opened deposit in the Yale district, British Columbia.

The total shipments during 1918 were 7,362 short tons, valued at $135,712, as compared with 4,249 tons, valued at $68,756, in 1917.

Eight properties were operated in the Madoc district, and the average value of shipment was $18.15, as compared with $16.08 in 1917. Prices have varied with the grade of the product from $15 to $30 per ton. In addition to the Madoc occurrences, a small tonnage is reported to have been mined in the township of Cardiff.

The Consolidated Mining & Smelting Co. is operating the "Rock Candy" fluorspar deposit on Kennedy Creek, Kettle River, Yale, British Columbia. The company reports very favorable indications for a large tonnage in excess of their own requirements for export.

Canadian steel companies use from 10,000 tons to 15,000 tons per annum.

[1] Preliminary report of the mineral production of Canada during the calendar year 1918: Canada Dept. Mines, Mines Branch, 1919.

GREAT BRITAIN.[1]

According to the official report[2] of output of mines and quarries issued by the Home Office at London, there were produced in Great Britain in 1917, the latest year for which statistics are available, 64,874 long tons of fluorspar, valued at $177,442, or $2.74 a ton, compared with 54,731 long tons, valued at $90,989, or $1.66 a ton, in 1916.

SWITZERLAND.[3]

Sembrancher, a small village on the Martigny-Orsières line (Valais), has just made itself conspicuous by the rediscovery of a lead stratum which had been worked in the sixteenth century and by the discovery of a precious mineral, the spath-fluor [fluorspar].

The mines are situated on the right bank of the Dranse, below Sembrancher, to the side of the Grand St. Bernard route and the railroad Martigny-Orsières. The stratum crosses the Mont-Chemin, and it is believed that there exist more strata parallel to the one just discovered.

In the principal mine, called the Trappist mine (from the time of Napoleon, when Trappist monks had taken refuge in the valley) the thickness of the stratum, mixed between layers of gneiss and schistoid porphyry, is of an average of 1 meter.

The principal mineral found is galena, composed in variable proportions of lead and argentiferous sulphur. The remainder is composed of a mineral easy to break, which was considered until now by geologists as baryta or quartz. But this is not the case and the mineral in question is spath-fluor or fluorina, almost pure, which, mixed with sulphuric acid, gives fluor-hydric acid, which has the property of attacking glass.

Until the present time Switzerland was tributary to abroad, and more especially to Thuringia (Germany), for the spath-fluor she needed.

PRODUCTION IN PRINCIPAL COUNTRIES.

The principal sources of the present world's supply of fluorspar are the United States, Great Britain, Germany, France, Austria-Hungary, Canada, Australia, and Spain, but the bulk of the world's supply comes from the United States and Great Britain, the former being also the chief consumer. In the following table is given the production of fluorspar in those of the above-mentioned countries for which statistics are available. No statistics are available for Germany and Austria-Hungary, but the annual pre-war output of these countries was about 20,000 tons and 8,000 tons, respectively.

Fluorspar produced in some principal countries, 1913–1918, in metric tons.

OPTICAL FLUORSPAR.

Fluorspar suitable for optical purposes has occasionally been found in mines in southern Illinois, western Kentucky, and some Western States. During 1918, 371 ounces of optical fluorspar was produced from material mined in Riverside County, Calif., and Crittenden County, Ky. Several good specimens were received by the Survey during 1918.

Notes on the properties, uses, quality, and value of optical fluorspar and suggestions as to developments were given in the chapter on fluorspar in Mineral Resources for 1917, Part II, pages 301–302, in the chapter on gems and precious stones in Mineral Resources for 1918, Part II, page 13, and in Bulletin 38 of the Illinois Geological Survey, 1918.

FLUORSPAR IN RELATION TO THE WAR.

A special paper on fluorspar as a war mineral was issued by the Geological Survey two years ago.[1] That paper discussed the character and occurrence of fluorspar, its preparation and uses, the trend of the industry preceding and during the first three years of the European war, and the available domestic supplies of the mineral.

As the war was practically terminated in 1918, it is now of interest to summarize the part played by fluorspar during the whole of the war period, but the reader is referred to Bulletin 666 for many details for which there is not space here.

Principal war uses.—Fluorspar found its principal applications in war, as in peace, in the metallurgic, ceramic, and chemical industries, but the greatly increased demand for certain products of these industries led to a phenomenal growth in the consumption of this useful mineral. The number of ways in which it is utilized was also enlarged. In the metallurgic field 70 to 80 per cent of the output of fluorspar is used as a flux in the manufacture of basic open-hearth steel. The production of open-hearth steel increased more than 100 per cent from 1914 to 1918. Fluorspar is also finding considerable use as a flux in the manufacture of ferroalloys in the electric furnace. The output of electrically produced ferroalloys, including ferromaganese, spiegeleisen, ferrochromium, ferrosilicon, ferrotungsten, ferrovanadium, ferrotitanium, and ferromolybdenum, increased more than 3,000 per cent from 1914 to 1918. A special use for flourspar that was developed during the war was in the recovery of by-product potash from Portland cement kilns. A demand that was only partly supplied arose for clear, flawless crystals of fluorspar for use in the lenses of optical instruments.

Domestic supplies.—Domestic deposits of fluorspar were heavily drawn upon during the war, but they proved adequate to supply the demand. Imported spar, however, was readily sold whenever it became available, and it was needed at times to relieve shortages caused by difficulties in mining and transportation. High prices stimulated exploration for new deposits; many were discovered in the Western States and some in Kentucky and Illinois, and

[1] Burchard, E. F., Our mineral supplies—Fluorspar: U. S. Geol. Survey Bull. 666–CC, Oct. 2, 1917.

there were new developments of hitherto unworked deposits in most of the producing States. The number of producers of fluorspar increased from approximately 19 in 1914 to about 119 in 1918. Continuous increase in output and in consumption of fluorspar during the war years is shown in the tables and curve. The output of 263,817 short tons in 1918 shows an increase of 177 per cent over the output of 1914, which was 95,116 tons, and the apparent consumption during the same period showed an increase from 105,321 tons in 1914 to 276,389 tons in 1918, or 162 per cent. Imports have remained nearly stationary, the annual average for the five war years having been about 11,000 short tons, compared with about 31,000 short tons for the years 1910 to 1913, prior to which records are not available.

The initiative in speeding up production of fluorspar in response to the demands of war was taken entirely by private interests. Government encouragement was not necessary beyond placing fluorspar mining in a preferred class in 1918 in order to assist the industry to hold at least a part of the labor necessary to the operation of the mines. Labor conditions, however, were far from satisfactory, for sufficient miners were not available and most of those who could be employed were inexperienced.

It was pointed out in Bulletin 666 that the fluorspar deposits in Illinois and Kentucky could be depended upon to supply for many years a demand much greater than normal and that other States possessed deposits that might be drawn upon to supplement the supply from the larger deposits for a considerable period. It was also stated that if demand should ever greatly exceed the supply from present domestic sources a considerable quantity of spar might be obtained by saving the concentrates at metalliferous mines. This procedure evidently did not become necessary, but it should be considered in connection with future economies, as the use of fluorspar in western smelting plants is very likely to increase.

CRYOLITE.[1]

The entire supply of natural cryolite used in the United States is imported from Greenland. Some artificial cryolite is understood to be produced in the manufacture of aluminum, but it is not reported as marketed commercially, and no statistics are available as to its output.

The quantity of cryolite reported to have been imported for consumption in the United States in 1918 was 1,950 long tons, valued at $97,500, compared with 4,383 tons, valued at $218,500, in 1917. The average value per ton at the Greenland port of shipment was $50 in 1918, compared with $49.86 in 1917. Cryolite is imported free of duty.

[1] Data on the character, source, mining, and use of cryolite are given in a paper by C. P. Bernard, entitled "The cryolite mine at Ivigtut, Greenland" (Min. Mag., London, April, 1916, pp. 202–203); also in the chapter on fluorspar and cryolite in U. S. Geol. Survey Mineral Resources, 1916, pt. 2, pp. 322–323, 1919.

The annual imports of cryolite, beginning in 1894, as compiled from the records of the Bureau of Foreign and Domestic Commerce, are shown in the following table:

Cryolite imported and entered for consumption in the United States, 1894–1918.

Year.	Quantity (long tons).	Value.	Average price per ton.	Year.	Quantity (long tons).	Value.	Average price per ton.
1894 [a]	12,756	$170,215	$13.34	1907	1,438	$28,902	$20.10

PEAT.

By C. C. Osbon.

INTRODUCTION.

The progress of the domestic peat industry since it attained commercial proportions in 1908 constitutes an interesting phase of the development of our mineral resources. Though extensively used as fuel in Europe and widely known in the United States as a potential source of heat and power, peat has been unable in most parts of this country to compete with coal, and consequently many peat operators have directed their attention to the uses of peat in agriculture, with the gratifying results recorded in this report. Peat fertilizer first entered the markets in commercial quantities in 1908 and stock-food peat in 1912, and though there is still some prejudice against the use of these products the agricultural branch of the peat industry has been successful and the quantity of fertilizer and stock-food peat annually produced is increasing. In 1918 peat fuel for the first time since 1914 entered the market in commercial quantity.

The notable increase in the output of peat in recent years, and especially in 1917 and 1918, is ascribed to the shortage and high price of coal and nitrates, to the nation-wide demand for increased production of food, to a better understanding of the nature of peat, and to the application of bacteriology to the cultivation of crops. It is believed that these conditions, though in part created by the war, will in large measure continue to exist in this country, that the demand for peat products will correspondingly increase, and that peat will maintain and even better the position it has taken in 1918 in the industrial progress of the United States.

PEAT INDUSTRY.

GENERAL CONDITIONS.

The greatest activity and expansion in the history of the domestic peat industry took place in 1918. The output of crude peat far exceeded the quantity produced in any preceding year, and nearly all branches of the industry shared in the increase. Large quantities of fertilizer and stock food were manufactured from peat, but the most striking development of the year was the production of more peat fuel in New England than has been manufactured commercially in the entire United States in all preceding years. Almost equally striking were the large quantity of peat moss produced and the widespread interest manifested in our peat resources, which had heretofore been popularly regarded as of little value.

The total number of plants at which peat was commercially produced in 1918 was 25, an increase of 7 over the number operating in 1917. All the plants that operated in 1917 except four contributed to the output of peat in 1918, and 11 that were not represented in 1917 reported commercial production. Many new companies were organized in 1918, but did not complete their preliminary work in time to contribute to the year's output. Some stated that they could not obtain necessary machinery, but it seems that this situation has improved. As illustrated by Plate III, the plants known to be operating in 1918 were distributed as follows: California, 2; Connecticut, 1; Florida, 1; Georgia, 2; Illinois, 2; Indiana, 2; Maine, 1; Massachusetts, 3; New Hampshire, 1; New Jersey, 4; New York, 4; North Carolina, 1; and Pennsylvania, 1. Peat moss was also gathered by hand in Washington, Oregon, and Maine.

Nearly all producers reported that the demand for peat exceeded the supply, and it was stated by some that on account of meager facilities they were unable to fill the orders of their regular customers.

Many peat plants that operated in 1918 made improvements in order to increase production in 1919.

PRODUCTION.

CRUDE PEAT.

The quantity of crude air-dried peat produced in the United States in 1918 was 151,521 short tons—54,158 tons, or nearly 56 per cent, more than the record output of 97,363 tons in 1917.

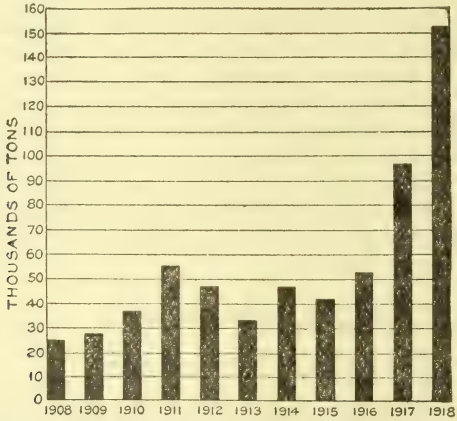

FIGURE 59.—Diagram showing development of the domestic peat industry, 1908–1918.

Nearly all producers of crude peat in this country use their entire output in the manufacture of peat products, and it was therefore impossible to determine accurately the value of the raw material. However, the average price received for all peat products in 1918 was $9.76 a ton, and the gross market value was $1,047,243, a gain of $2.47 in average price per ton and of $337,343, or approximately 48 per cent, in gross market value compared with 1917.

The accompanying tables and figure 59 show that the output of crude air-dried peat has materially increased in recent years.

Crude air-dried peat produced in the United States, 1908–1918.

Year.	Quantity (short tons).	Year.	Quantity (short tons).
1908	[a] 24,800	1914	47,093

PEAT PRODUCTS.

FERTILIZER.

The largest and most successful branch of the peat industry is engaged in the production of peat for a direct fertilizer and for a nitrogenous ingredient of commercial fertilizers. Of the 25 plants that produced peat in 1918, 19 used air-dried peat in the manufacture of fertilizer, the quantity of peat utilized, as reported to the United States Geological Survey, being 79,573 short tons. Compared with the output in 1917 this quantity is less by 12,690 tons, or about 14 per cent, but it exceeds the quantity used in 1916 by 31,467 tons, or about 65 per cent.

The average price received for the peat in 1918 was $9.74 a ton, a gain of $2.60 a ton over the average price received in 1917. Though there was a slight decrease in output in 1918, the increase in price was sufficient to make the total market value of the production, amounting to $775,313, exceed the value of the output in 1917 by $116,813, or nearly 18 per cent.

Of the total quantity of peat used in manufacturing fertilizer in 1918, 7,356 tons, valued at $64,170, or about $8.72 per ton, was bacterized.

The increasing acreage of land tilled, the shortage and high price of commercial fertilizers, and the better understanding of the nature of peat, of crop adaptations, and of soil bacteriology in recent years warrant the prediction that the peat-fertilizer industry will soon reach a high position among the mineral and allied industries of the United States related to agriculture. Successful machinery for producing peat fertilizer is referred to on page 342 of this report.

STOCK FOOD.

The quantity of peat used in manufacturing stock food in the United States in 1918 was 7,096 short tons, valued at $106,935, or an average price of $15.07 a ton. Compared with 1917, the output in 1918 was greater by 1,996 tons, or 39 per cent, and the value was greater by $55,535, or 108 per cent. Four peat producers manufactured stock food in Illinois and New York in 1918, compared with three in 1917.

FUEL.

Several of the experimental peat-fuel plants in the New England States mentioned in the survey report for 1917 [1] reached the stage of commercial production in 1918 and contributed 20,567 short tons of air-dried peat, valued at $164,745, or an average price of $8 a ton, to the country's fuel supply. Some hand-cut peat was produced by the owners of small bogs for home use, but this output is not included in the figures given. Though the output of peat fuel in 1918 was relatively small and was due largely to the coal shortage, it exceeded the quantity produced in all preceding years and indicates that the New England States, because of their cold climate, extensive manufacturing industries, large population, and the high cost of coal, offer promising possibilities for the development of a successful peat-fuel industry. Most of the producers in 1918 used the air-drying machine process. It is understood that peat fuel machinery, which was scarce in the United States in 1918, may now be readily obtained. A description of the methods of manufacturing peat fuel that have been most successful both in Europe and in this country is given in Bureau of Mines Bulletin 16.

OTHER PRODUCTS.

Large quantities of peat or sphagnum moss were produced and utilized in this country in 1918 for stable litter, packing material, and surgical dressings, and several hundred thousand acres of peat soils were also used for the growth of both general and truck crops. It is understood that the stable litter was produced by the owners of small bogs for their own use, but that the packing material was sold to florists and nurserymen. According to J. W. Hotson,[1] under whose direction peat moss was collected in the Northwestern States for surgical use, 595,540 peat moss pads were prepared from October, 1917, to November 11, 1918, by the northwestern and Atlantic divisions of the American Red Cross. Most of the moss was gathered by volunteer labor from the bogs of Washington, Oregon, and Maine, and the pads were used in military hospitals both at home and abroad. At first the surgeons of the United States Army were not disposed to use the pads, but later the value of sphagnum was universally recognized. The gathering of moss and preparing of pads was largely curtailed when the armistice was signed, but it seems that the value of peat moss as an absorbent and disinfectant demonstrated during the war will not be forgotten and that it should be able to compete commercially with cotton for these purposes in normal times. A brief discussion of the best kinds of peat moss and of the method of gathering it is given in the report by Hotson.[1] As the quantity and value of the peat moss produced in 1918 and used for surgical dressings could not be ascertained, it is not included in the accompanying tables.

CONDITIONS IN PRINCIPAL STATES.

California.—Peat was produced by two companies in San Bernardino County, Calif., in 1918, and was used for the cultivation of citrus trees. One of these companies enriched its product by treatment with nitrifying bacteria. It is reported that treated peat, known locally as "humus," is gaining favor in the citrus industry of California and that two new peat plants were erected in 1918 but had not reached the stage of commercial production at the end of that year. No response was received to statistical inquiries directed to the Pacific Peat Fuel Co., San Francisco, Calif., mentioned by the Survey in 1917 [2] as experimenting with the Herbein briqueting

process. Muck soils are used to a small extent in farming in California.

Connecticut.—Edward A. Beals, of Hartford, Conn., has made many energetic attempts to establish a peat industry in Connecticut, but although the State contains large deposits and plants have been erected, no market for peat fuel has thus far been created. Several years ago a peat plant was installed by the Connecticut Co., a subsidiary organization of the New York, New Haven & Hartford Railroad Co., at its Burrville power house, but after several trials the project was abandoned. A. N. Pierson, a florist of Cromwell, Conn., also attempted to substitute peat for coal in heating his greenhouses, but the raw peat selected contained an undue proportion of silica, which melted in the furnace and interfered with the draft. However, it is understood that a further effort is being made to produce peat fuel commercially in Connecticut, and it is hoped that the project will be successful.

Florida.—Two companies, one near Pablo Beach and the other at Citra, have manufactured peat fertilizer commercially in Florida for many years. In 1918, however, because of the shortage and high cost of labor, the former plant discontinued operations and the latter, operated by the Alphano Humus Co., of New York, N. Y., contributed the only peat that entered the markets from Florida in 1918. Prospective producers were hampered by inability to obtain necessary machinery. Reclaimed peat land is widely used by the agricultural industry of Florida.

Georgia.—Peat was produced in Georgia in 1918 by two plants located at Pineora and Tifton. The work was largely experimental, but it is said that the market for peat in Georgia is excellent, and that machinery is being installed in these plants to produce a large quantity of peat fertilizer in 1919.

Illinois.—As in previous years, two operators in Illinois contributed to the output of fertilizer and stock-food peat in 1918. One of them produces more stock-food peat than any other peat operator in the United States and is second in the production of fertilizer peat. Truck crops are extensively raised on the peat soils of Illinois, and tough peat-marsh grasses are harvested and used for the manufacture of rugs and for packing ice.

Indiana.—The contribution of Indiana to the peat industry of the United States in 1918 consisted of fertilizer peat produced from bogs near Fort Wayne and Lakeville by the Virginia-Carolina Chemical Co. and the St. Joseph Humus Co. The output of the former company was used in the manufacture of commercial fertilizer, but the latter's production was sold to florists and golf clubs and used as a direct fertilizer for potting plants and for use on lawns. The plant of the Virginia-Carolina Chemical Co., at Fort Wayne, Ind., was destroyed by fire in 1918. Large crops of celery, onions, and other truck crops are grown upon reclaimed peat land in Indiana.

Maine.—The output of peat in Maine in 1918 consisted of a small quantity of fuel produced by one operator near Lewiston, Androscoggin County, and sold locally. Others stated that they were awaiting the results of the experimental work of the Canadian

Government at Alfred, Ontario, prior to erectng plants. A small quantity of peat moss was also gathered from the bogs of Maine in 1918 and used by the American Red Cross in the preparation of surgical dressings.

Massachusetts.—The output of air-dried peat in Massachusetts in 1918 amounted to 18,500 tons, valued at $160,200, and consisted of both fertilizer and fuel produced from bogs near Peabody, North Adams, and Shirley. One producer reported that some consumers were doubtful of the value of peat fuel; another stated that the demand exceeded the supply. It is understood that several companies were organized in 1918 but did not complete preliminary work in time to contribute to the State's output in that year. C. D. Jenkins, of Boston, has been one of the most active peat producers in Massachusetts for many years and has designed and patented peat-fuel machinery.

Michigan.—Although no peat was sold in Michigan in 1918, large-scale experimental work was done by Louis P. Haight, of Muskegon, who proposes to produce bacterized peat and use it in tilling sandy soil. A large peat-fertilizer plant was erected by the Fertile Chemical Co. at Chassell, Mich., in 1918. Though this company did not produce peat that year, it will probably contribute a substantial quantity of fertilizer to the output in 1919. To meet the demand for peat-fuel machinery in 1918 plans were designed and machinery was manufactured by the C. A. Willmarth Co. and J. Campbell Morrison, of Detroit, Mich., and by Herbert Garnett, of Grand Rapids, Mich.

Minnesota.—Although Minnesota contains almost half of the workable peat in the United States, no peat products were manufactured in that State in 1918. It is understood that the Hamm Brewery Co., of St. Paul, F. A. Wildes, the State superintendent of mines, and Henry W. Hindshaw, of Hibbing, experimented with peat in 1918. Attempts are being made to obtain funds from the State legislature for experimental work on peat in cooperation with the United States Bureau of Mines. A process was reported by Mr. Wildes by which peat, when mixed with fine iron ore and flue dust and burned, produces an ore of good texture. It is stated that the process will be tried on a large scale if funds can be obtained. Peat soils are extensively utilized in Minnesota for the cultivation of crops.

New Hampshire.—The contribution of New Hampshire to the output of peat products in 1918 consisted of a small quantity of peat moss gathered from a bog 25 acres in area and 10 feet deep, near Milford, Hillsboro County.

New Jersey.—The output of crude air-dried peat in New Jersey in 1918 amounted to 70,228 short tons, of which 26,213 tons, valued at $264,797, was used in the manufacture of fertilizer, and 44,010 tons, valued at $96,040, was placed in storage. Although peat is found in Bergen, Essex, Hudson, Mercer, Middlesex, Morris, Passaic, Somerset, Sussex, Union, and Warren counties, the entire output in 1918 was obtained by four producers from deposits in Sussex and Warren counties. More peat is produced in New Jersey than in any other State, and the largest producer is the Alphano Humus Co., of New York, N. Y. New Jersey supplies the New York mar-

kets with large quantities of truck crops produced by the cultivation of peat soils.

New York.—Approximately 3,501 short tons of air-dried peat, valued at $49,430, was produced by four operators in Dutchess and Suffolk counties, N. Y., in 1918, and used largely for the manufacture of fertilizer. Many of the largest truck farms in New York consist chiefly of drained peat lands.

North Carolina.—The contribution of North Carolina to the peat industry consisted of a small output produced by one operator from a deposit 250 acres in extent near Newbern, Craven County, and sold to a company in Richmond, Va., for the manufacture of bacterized peat. It is understood that the deposit was purchased by the Richmond company in February, 1919.

Pennsylvania.—Pennsylvania contributed a small quantity of peat from a bog near Espy, Columbia County, in 1918.

Other States.—Oregon and Washington contributed the mass of the peat moss that was used by the American Red Cross in the preparation of surgical dressings in 1918. In addition to the States mentioned in which truck crops are raised on peat soil Iowa, Ohio, and Virginia contain large areas of reclaimed peat land that is used by farmers for trucking.

IMPORTS.

In previous years peat moss has been imported into this country from Canada, Germany, and Holland, but in 1918, because of the shortage of ships, no peat moss from foreign sources entered the country. The decline in imports since 1913 recorded in the following table was probably caused by the war, and it is believed that with the return of normal conditions the import trade of the moss industry will be resumed.

Peat moss imported for consumption in the United States, 1913–1918.

Year.	Quantity (short tons).	Average price per ton.	Value.	Year.	Quantity (short tons).	Average price per ton.	Value.

1914	9,921	5.80	57,542	1917	506	9.81	4,965
1915	7,514	6.41	48,142	1918	.....	.....	.....

EXPORTS.

No exports of crude peat or peat products were reported in 1918.

CONSUMPTION.

It is estimated that 107,261 short tons of crude air-dried peat was used in 1918 for the manufacture of fertilizer, stock feed, fuel, and other peat products, compared with 97,869 tons in 1917. As the crude peat and peat products were produced by the same operators no accurate value can be assigned to the raw material. The quantity of peat actually consumed in the United States is not susceptible of accurate determination on the basis of the statistics collected by the Geological Survey. However, as no peat is exported from this country, so far

as can be ascertained, and as very little is held in storage, the sum of the quantity produced and the quantity imported provides an approximation of the quantity consumed that is not without value in the absence of more specific data.

STOCKS.

Approximately 44,260 short tons of crude aid-dried peat and peat products remained in storage in the United States at the end of 1918. In general peat products are marketed as quickly as possible, and hence only small quantities are kept in stock, but crude peat, because it can not be economically excavated and handled out of doors in wet or cold weather, must be produced during the air-drying season, which begins in April and ends in October. Sufficient raw material must therefore be produced in that period to supply peat-drying plants for about five months.

COMMERCIAL FACTORS.

A full discussion of the factors controlling the profitable utilization of a peat deposit is here given in order to indicate the causes of past failure. Some attempts made in this country to produce peat on a commercial scale have not been successful, but the failures appear to have been due not to a lack of a market for the product, but to the lack of sufficient capital, to the inexperience of operators, and to the injudicious choice of deposits, plant sites, manufacturing processes, and machinery. All these factors should be carefully considered by prospective producers.

LOCATION.

The location of the deposit is the prime factor in the successful operation of a peat plant. Many deposits containing peat suitable for commercial use are known in all the peat areas, but under present conditions in the United States only deposits located near the

markets and where cheap labor and transportation may be obtained can be profitably developed. Thus the conditions for producing peat fuel successfully are most favorable in Minnesota, Wisconsin, northern Michigan, and the New England States, regions which contain no known coal fields and which, because of their cold climate and extensive manufacturing industries, consume large quantities of fuel. In the southern part of the Atlantic coastal region there are likewise no local sources of other mineral fuels, but the climate is mild and the demand for fuel relatively light compared with that in the Northern States. (See Pl. III.) Peat fertilizer plants should preferably, of course, be located near the agricultural districts and the largest commercial fertilizer plants. As peat is not well known in this country, a market will have to be created in many places, but if high-grade products can be sold at a low price it should be possible to build up successful industries.

QUANTITY AND QUALITY.

The prospective deposit should be carefully surveyed to ascertain whether it contains a sufficient quantity of good peat before plans are made for the erection of a plant. Typical samples should be analyzed to ascertain whether the peat is of suitable quality for the purpose desired. One of the great handicaps of the peat industry has been the lack of uniformly good quality, and, as the success of a plant depends upon the kind of raw material used, due care should be observed in its selection.

The requisite size of the deposit will, of course, vary with the capacity of the plant erected, but it is generally unwise to erect a plant on a deposit less than 100 acres in area and 4 feet in depth. The average peat deposit will yield approximately 200 tons of air-dried peat to the acre-foot. The product obtained by multiplying the area in acres by the depth in feet by 200 gives the approximate tonnage of peat in a deposit. The topographic maps issued by the United States Geological Survey show many important peat deposits in this country as swamps and marshes, the area of which may be readily estimated from the map. The dimensions of deposits that have not been mapped should be carefully measured. Although peat deposits less than 4 feet deep may be advantageously used for the growth of crops, they are of little value as a source of fertilizer or fuel. Numerous depth tests should therefore be made and the average thickness of the peat determined. An earth auger may be employed for this purpose, but a sampling tool especially designed by the late C. A. Davis[1] for testing the depth of peat deposits is superior to the earth auger for sampling peat.

Samples of peat should typify the entire deposit from which they are taken or a definite portion of it. Specimens consisting of material taken at depth intervals of 1 foot and at areal intervals of 100 yards in a small shallow deposit are usually adequate to represent the general composition of the deposit. It is obviously impossible to obtain a typical sample of the peat in a large deep deposit. Such a deposit should be divided into blocks and typical samples

[1] Davis, C. A., The uses of peat for fuel and other purposes: Bur. Mines Bull. 16, p. 71, 1911.

should be obtained from each block. In large deposits samples are generally taken at depth intervals of 2 feet and areal intervals of a quarter of a mile. The material taken in each block may later be mixed in order to obtain a representative composite specimen. Structural features should be noted as deposits are sampled, and if the peat is distinctly bedded, samples should be taken from each bed and separately analyzed. If the lower strata contain a large proportion of inorganic impurities, that fact should be noted, in order that these strata may be avoided in excavation. As analyses of dry peat show its chemical composition and fertilizer and fuel values as well as analyses of wet peat, it is unnecessary to place samples taken for analyses in air-tight containers. For a simple test about 10 pounds of raw peat is required, and for a detailed chemical analysis about 40 pounds. Samples should ordinarily be air-dried to a moisture content of about 50 per cent in the field and sent to the laboratory in canvas bags. However, if it is desired to identify the plant remains, small specimens should be placed in sealed bottles or air-tight soil cans so that the peat may later be examined under the microscope in its native condition.

Black, thoroughly decomposed, friable peat from a deposit that has been well drained, aerated, and successfully cultivated for several seasons is usually suitable for an ingredient of commercial fertilizers or, when inoculated with nitrifying organisms or composted with manure, for a direct fertilizer.

Some evidence of the fuel value of peat may be obtained from a small sample that has been macerated in the hands, pressed into a cake, and allowed to dry in the sun. If it is easily disintegrated and plastic while wet, it may be readily worked in a peat machine, and if, when dry, the cake is dense, tough, and hard, the peat will probably make good fuel unless the ash content is too high. However, if the dry peat cake is soft, fibrous, and easily crushed, the peat is not well adapted to the manufacture of fuel.

The heating value and ash content of prospective peat fuel for home consumption may be determined by a simple practical test. A typical sample should be taken from the bog, thoroughly macerated, dried, and weighed. If when burned in an ordinary heating stove the heat generated is a little less than that produced by ordinary bituminous coal, and if after complete combustion the weight of the accumulated ash does not exceed 20 per cent of the weight of the dry peat put into the stove, its usefulness as domestic fuel is established.

PREPARATION OF SURFACE.

The surface of peat deposits must be prepared by draining and clearing before the peat can be removed. The water level should be reduced by a system of tile drains or ditches to a point between 2 and 3 feet below the surface. Only deposits that can be cheaply drained should be selected. Many bogs are easy to drain, but the drainage of some peat-forming basins is so difficult that their surfaces can not be economically prepared for peat production by known methods. Marsh deposits and bogs are cleared by removing the living grasses and mosses and grubbing out the

shrubbery. The clearing of swamps overgrown by mature trees is expensive, but this expense is sometimes offset by the value of the timber obtained.

PROCESSES AND MACHINERY.

The failure of many peat plants in the United States has been due to improper choice of manufacturing processes and machinery. The excess moisture in the peat must be eliminated at as early a stage as possible in the manufacturing process. This can be most economically done by evaporation on the surface of the deposit. Whether for the manufacture of fertilizer or fuel, machinery of proved efficiency must be selected. Field equipment propelled by caterpillar drives seems well suited for use on boggy surfaces. The most successful peat-fuel machinery that has been used in North America was designed by the Canada Department of Mines and recently operated at Alfred, Ontario. Mr. John N. Hoff, of New York, N. Y., is the inventor of peat-fertilizer machinery that has been successfully used by him on a deposit near Great Meadows, N. J., for several years. Experimental work is always commendable if properly limited, but the methods and machinery that have proved successful in North America and in the peat-producing countries of Europe should be given first consideration. The peat industry of European countries is well developed, and detailed information concerning European peat machines is available in Bureau of Mines Bulletin 16 and in the report of the Canada Department of Mines cited on page 350.

MARKETS.

The principal markets for fertilizer peat are in or near some of the agricultural States, notably Maryland, New York, New Jersey, Illinois, Virginia, Kentucky, Tennessee, and Florida, and the largest buyers are the manufacturers of commercial fertilizer, brokers in fertilizing materials, florists, and farmers. Markets could probably be created in all the agricultural States. Stock-food peat is sold to manufacturers of stock feed and to growers of live stock. Many of the peat deposits in this country are located in regions remote from the coal fields, and it seems that markets for peat fuel might therefore be created in some of the peat States.

DEFINITIONS.

The terms "peat" and "muck" are often used interchangeably to designate either of those materials. This practice is confusing and should be discouraged. Peat is the partly carbonized organic residuum produced by an arrest in the decomposition of roots, trunks, and leaves of trees, twigs, shrubs, mosses, and other vegetation covered or saturated with water. It contains a large proportion of the carbon of the original vegetable matter, and in most peats the vegetal structure is visible without the microscope. Peat is usually acidic, and the quantity of inorganic matter is materially less than that of the organic, pure peats often containing less than 4 per cent of inorganic impurities. Muck is uncarbonized organic soil containing a large proportion of inorganic mineral. However, it is difficult to

define the line of demarkation; peat may grade into muck and muck into peat. If the material will ignite and burn freely when dry it is usually considered peat.

ORIGIN.

The formation of peat is dependent on conditions favorable to the profuse growth of plants and to the escape of the plant débris from complete decomposition by bacterial and chemical action, conditions which are governed by topography and climate. If the land surface contains depressions, or gently sloping, poorly drained areas in which water may collect and permanently stand, and if the temperature of the air and the soil is low in summer or the humidity of the air is high enough to prevent rapid evaporation, peat-forming plants will flourish.

Glaciation was the dominant factor in the distribution and origin of most of the peat deposits in this country as well as of many in Canada and Europe. These deposits for the most part occupy lakes, marshes, and ponds formed during the last glacial epoch. Another factor in the distribution of peat is the character of the surface rock, which in many regions determines the topography. When the earth's surface, composed of rock formations that vary in hardness, is subjected to stream or glacial action, surface depressions develop. Some of the peat deposits of the New England States owe their origin to this diversity of surface rock. Basins in which peat may accumulate are also formed in a few limestone regions by solution.

Next in importance to glaciation in peat formation are wave and stream action and coastal subsidence. Many peat deposits of salt and fresh-water origin are found in drowned valleys where the coast has subsided and land-locked lagoons have been formed behind barriers erected by wave action or where deltas have been built up and the coast has subsequently risen, resulting in the formation of flat, imperfectly drained inland areas. In some places salt-marsh peat underlies peat of fresh-water origin and in others the reverse, indicating the fall and rise of the seacoast.

Abundant and evenly distributed rainfall, high humidity, and a cool or moderate temperature are the most favorable climatic conditions for fresh-water peat formation. All these conditions are present in the northern peat region and in varying degrees in the coastal region. Peat sometimes forms in the Frigid Zones, but not extensively, and also in the Torrid Zone, although owing to the high temperature, plant débris decays there rapidly, and despite profuse plant growth peat accumulates slowly and therefore contains a high percentage of inorganic matter. For good tropical peat a heavy rainfall well spread through the year is essential.

On account of the good drainage no peat of consequence is found in the Appalachian and Rocky Mountain regions, nor, because of scanty rainfall, in the area between the Rocky Mountains and Mississippi River, except in Minnesota and Iowa. Contrary to the general belief, there is little peat in commercial quantities in the lower Mississippi Valley, a condition due partly perhaps to high temperature, but mainly to the vast amount of alluvium carried and deposited from time to time by Mississippi River and its tributaries.

Although hundreds of different plants have been identified in the bogs and swamps of this country, comparatively few contribute the mass of the vegetable débris from which peat forms. The most common are trees, heath shrubs, sedges, grasses, mosses, pondweeds, water lilies, reeds, cattails, and ferns. When given a favorable environment most of these plants multiply rapidly and soon predominate over their competitors; in fact, in some areas they grow so densely that man penetrates them with difficulty, and an immense quantity of dead vegetation accumulates annually.

One of the chief substances formed by plants during growth is cellulose, which consists of carbon, hydrogen and oxygen. These constituents are absorbed by the leaves from the atmospheric gases and by the plant roots from the soil. Cellulose, because of its complex composition, is an unstable compound and is attacked by fungi and bacteria rapidly decomposes. If at the end of the growing season the plant débris falls upon drained land it is vigorously attacked by these microorganisms, and the carbon and hydrogen of the cellulose unite with the atmospheric oxygen and with each other, forming carbon dioxide and water. In other words, if oxidation is unhampered, the organic matter will disappear in a relatively short time. If, however, the plant matter falls in large quantities into water or upon soil saturated with moisture, it undergoes a different change from the decay suffered by exposed vegetation. The atmospheric oxygen is largely excluded and as the activity of fungi and bacteria, which usually cause complete decay, is controlled by the supply of air, upon which they depend for their existence, decay is slow, and a large proportion of the fixed carbon is retained. The salient features in the evolution of peat from cellulose are the elimination of hydrogen and oxygen as water and of carbon and oxygen as carbon dioxide and the generation of methane. This is the process of carbonization.

If surface conditions are unchanged the process of carbonization is largely arrested with the formation of peat, and the accumulation of organic matter may exist indefinitely as peat unless the land is drained and decomposition again begins. If, on the other hand, the peat is deeply buried beneath superposed deposits, generally muds, sands, and limestone, and is subjected to pressure, with varying degrees of heat, lignite, bituminous coal, anthracite, and graphite are succeeding stages in the process of carbonization. It seems, therefore, that most coals of the common types were once peats, that most coal fields were formerly swamps, and that the formation of peat in the bogs and swamps of this country is an existing example of the first stage in the process of coal formation. It has been shown that deposits essentially similar were laid down in many parts of the United States during the Carboniferous period.

DISTRIBUTION AND QUANTITY.

The most extensive peat deposits in the United States are found in a region which lies east of the ninety-seventh meridian and north of an irregular line drawn eastward through the northern sections of Iowa, Illinois, Indiana, Ohio, Pennsylvania, and New Jersey, and approximately includes the area covered by the Wisconsin or last

MAP OF THE UNITED STATES SHOWING DISTRIBUTION OF PEAT DEPOSITS AND APPROXIMATE LOCATION OF PLANTS THAT PRODUCED PEAT IN 1918

glacial drift. (See Pl. III.) Many workable peat beds occur also in areas extending 25 to 50 miles inland on the Atlantic coast from New Jersey to southern Florida and along the gulf coast to the Mexican boundary, and there are a few workable beds of peat in the Pacific Coast States.

The areas of peat accumulation in this country may, therefore, be roughly assigned to two major regions, the northern or glacial and the coastal, and this subdivision, though partly geographic, expresses the chief differences in manner of formation and in the quality of the peat. The northern peat region includes Minnesota, Wisconsin, Michigan, New York, northern New Jersey, the New England States, and the northern sections of Iowa, Illinois, Indiana, Ohio, and Pennsylvania. This region is characterized by the presence of numerous small lakes and marshes formed as a result of glacial action during Pleistocene time, and by relatively low temperature and high humidity, and most of the peat originated in basins. Moss, sedge, grass, and tree peat are abundant, and much sphagum is found growing on bogs in Maine and in the northern counties of Minnesota, Wisconsin, and Michigan. The deepest and most extensive deposits in the New England States lie east of the Berkshire Hills and the Green Mountains.

The Atlantic coastal region embraces southeastern New Jersey, the eastern parts of Delaware, Maryland, Virginia, North Carolina, South Carolina, and Georgia, all of Florida, the southern parts of Alabama, Mississippi, and Louisiana, and coastal Texas. The nearness of the ocean causes heavy rainfall and high relative humidity in this region, and the deposits are found in drowned valleys and lagoons formed by the gradual subsidence of the Coastal Plain and by wave action and on flat, imperfectly drained areas farther inland. The region is typified by many fresh and salt water marshes and by swamps in which the deposits have been formed largely by trees, marsh grasses, and other plants, some of which tolerate salt water around their roots. On the Gulf coast, owing to the hot climate, dead vegetation decays rapidly, and as the peat therefore accumulates slowly it contains much ash. The most extensive peat deposits in the coastal region occur in Florida.

Although there are a few peat deposits on the New England coast that are related in origin and composition to those classed in the coastal region, by far the most numerous bogs of the northeastern States are of the glacial-lake kind, and the region as a whole should be so considered in a classification of the major peat regions.

The known workable peat beds of the Pacific coast region occur in Orange, Los Angeles, and San Bernardino counties, Calif., and in the basins of several of the lakes and rivers of Washington and Oregon, but peat deposits of commercial extent are comparatively rare in this region.

The total quantity of good peat in the United States, exclusive of Alaska, was estimated in 1909 to be about 12,889,000,000 short tons,[1] but recent field investigations by E. K. Soper and others seem to justify an increase of this figure to 13,826,000,000 tons.

[1] Davis, C. A., Peat resources of the United States exclusive of Alaska: U. S. Geol. Survey Bull. 394, pp. 65–66, 1909.

Approximate distribution and quantity of air-dried peat in the United States.

	Short tons.
Northern region	11,053,000,000
Atlantic coastal region	2,701,000,000
Other regions	72,000,000
	13,826,000,000

USES.

WAR-TIME USES AND POSSIBILITIES.

A review of conditions in the peat industry during the year in which the great world war terminated seems a fitting place to record the war-time uses and possibilities of peat and its relation to the welfare of a warring nation. Peat and peat moss are used in the manufacturer of fertilizer, fuel, and surgical dressings, products which, though necessary in time of peace, are vital in time of war.

Peat was extensively utilized in nearly every European country during the war to supplement inadequate supplies of coal and fertilizer, and many governmental plants were erected for its production. In some countries prices were fixed to prevent extortion and measures were adopted by the Governments to stimulate production. As imports of coal into some countries were greatly curtailed, much suffering and financial loss resulted, despite the large output of peat from domestic sources, but because of this increased production of peat fuel, which was extensively used by domestic consumers and in hospitals, great hardship was avoided by some people and many lives were saved.

The collection of sphagnum, or peat moss, was another important war activity that assumed large proportions in Europe. The gathering of surgical moss by volunteer labor was considered a patriotic duty in England and Scotland, and before the armistice was signed the question "Are you gathering moss?" assumed the nature of a byword. Millions of moss pads were used during the war, and the supply of cotton available for the manufacture of munitions was thus greatly augmented.

In the United States, on account of our immense coal reserve and large output of cotton, peat did not take a large part in war activities, but by furnishing nitrogen to the fertilizer industry it released nitrates for the manufacture of explosives, and was thus of some assistance in the prosecution of the war. More than half a million peat-moss pads were prepared in this country and sent to domestic and foreign military hospitals. It is understood that a plant for the manufacture of nitrate from peat was in process of erection when the armistice was signed. Shortly after this country entered the war the United States Geological Survey directed attention to the vast peat deposits of this country located in regions remote from the coal fields and suggested the production of hand-cut peat fuel for local use by the owners of small deposits. It appears from reports that many people responded and that more peat fuel was produced in the United States in 1918 than in all preceding years. Our peat deposits are of great potential value as a source of fuel, fertilizer, nitrate, and antiseptic material.

PEAT IN AGRICULTURE.

FERTILIZER.

The peat deposits of the United States are one of the few extensive known domestic sources of nitrogen that can be converted into plant food at a price that is economical to the farmer. The average nitrogen content of domestic raw peat is about 2 per cent, although many peats contain more than this quantity. This nitrogen may be recovered in the form of ammonium sulphate or may be made available for plant food without extracting it from the peat. Arguments are often advanced against the direct use of peat as a source of nitrogen in soil fertilization because all of this element shown by chemical analysis is not readily available for plant food, but this criticism seems to be based on a misconception of the nature of peat. It is true that only a part of the nitrogen shown by analysis can be immediately used for food by plants, but it is equally true that a chemical analysis of peat is not a fair test of its value as a fertilizer and that the total quantity of potential soluble nitrogen formed and released by bacterial action from time to time after the peat has been applied to the soil is in the aggregate much greater than the percentage found in some commercial fertilizers.

Fortunately all of the nitrogen in peat is not soluble at one time, or it would leach out and the potentially rich black peat soils of this country would be unproductive.

The largest use of peat in the United States for the cultivation of crops, exclusive of the direct cultivation of peat soils, is in the form of a nitrogenous ingredient of commercial fertilizers. In fact some of the large manufacturers of commercial fertilizer rely on peat to contribute a substantial proportion of the nitrogen content of their product. It is said that good peat when properly prepared for this purpose will contribute nearly 5 per cent of its total weight as nitrogen.

A new process for the commercial application of bacteriology to soil fertilization was reported in 1918 by John N. Hoff, of New York, N. Y. According to his method the peat is cultivated for several seasons, excavated, air-dried, neutralized or made slightly alkaline, and is used as a carrier and energizer of several varieties of legume and other bacteria.

PEAT SOILS.

Peat soil when properly treated is one of the most fertile types of soil in this country. Owing to the abundance in previous years of well-drained land that could be more readily tilled, the peat and muck areas have been passed by; but with the rapid increase of our population and the advent of intensive soil cultivation the attention of agriculturists and others is now being directed to these neglected lands. In the eastern section of this country there is approximately 15,000,000 acres of peat and muck land supporting a growth of shrubs, tamarack, white cedar, birch, water maple, gum, and cypress, and only about 750,000 acres, or 5 per cent of the total area, has been reclaimed for agriculture. Secretary Franklin K. Lane, in advocating the reclamation of the swamp and cut-over timber lands of the

United States and their sale on deferred payments to discharged soldiers, sailors, and marines, said in substance in a recent statement for the press:

> There are approximately 200,000,000 acres of cut-over or logged-off timber land in the eastern half of the United States and, overlapping to a certain extent the cut-over lands, some 80,000,000 acres of swamp land located largely in the southeastern section of the country.
>
> To the ordinary observer the reclamation of these waste areas may seem difficult. The soil, however, is in many instances very fertile. For many years leaf mold containing humus has been accumulating, and once the stumps have been blown out and the land cleared of brush and brought under the plow, it is believed that these lands will prove among the most fertile of our agricultural resources. Like the Dismal Swamp in Virginia, or the Everglades in Florida, most of the swamp land in its present condition is unfit for human habitation. Consider this land cleared of its timber, adequately drained, and intensively cultivated, and some idea of its possibilities for the production of food will be obtained.

Raw peat soils, though too acidic for ordinary farming, are after they have been drained, cleared, freely aerated, and properly fertilized, especially well adapted to the production of vetch, redtop, millet, buckwheat, oats, corn, rye, the potato, the cranberry, the blueberry, the strawberry, and other acid-tolerant crops.[1] If properly treated with potash salts and with lime they are neutralized or made slightly alkaline and should then yield large quantities of red clover, timothy, blue grass, wheat, rutabagas, and other alkaline or neutral-soil crops. The greatest returns derived from the cultivation of peat, however, have arisen from its use as a truck crop soil. According to the Bureau of Soils,[2] cabbage, onions, celery, lettuce, spinach, carrots, beets, turnips, and peppermint are the most valuable crops that are grown on treated areas of peat. The acreage values of these crops so far surpass those of the general farm crops that the reclamation of any large areas of peat should be undertaken with the special object of their production.

The fertility of peat soil is chiefly due to its nitrogen and humus contents, to its affinity for moisture, and to its black color, which enables it to absorb heat. For the profitable production and sale of both general and special crops, it is desirable that such areas of peat as are close to large city markets and accessible to good transportation and cheap labor should be first reclaimed.

The first attempts to use peat lands for the growth of crops were made in the older agricultural districts of the Eastern States, notably New York and New Jersey. Some of the most productive farm lands in those States were formerly peat bogs and swamps. The truck farm of John N. Hoff near Great Meadows, Warren County, N. J., the well-known onion farms of the Wallkill River valley, Orange County, N. Y., and the Oak Orchard lands north of Batavia, N. Y., are reclaimed peat deposits. Thousands of acres of land in these States now under intensive cultivation are underlain by peat from 10 to 15 feet deep. Nearly half a million acres of peat land in the Dismal Swamp district of Virginia and North Carolina is successfully devoted to the growth of potatoes, corn, wheat, and other crops. An average of more than 30 bushels of wheat to the acre has been obtained for several years on the well-tilled farm of

[1] Coville, F. V. The agricultural utilization of acid lands by means of acid-tolerant crops: U. S. Dept. Agr. Bull. 6, 1913.
[2] U. S. Dept. Agr. Bur. Soils Cir. 65, pp. 13–14, 1912.

the Wallace Bros., in the Dismal Swamp, Va. Peat soils are also extensively used for crop cultivation in Minnesota, Wisconsin, Michigan, Iowa, Illinois, Indiana, and Ohio. Thousands of acres are already under cultivation, and millions may be reclaimed by proper drainage and clearing. In fact, the economic future of entire counties seems to be directly dependent upon the successful reclamation of peat bogs and swamps.

Many peat soils require careful fertilization before crops can be successfully grown upon them. This is especially true of deep peat, as the plants are unable to obtain certain necessary minerals from the subsoil. Potash is required by many peats, and phosphates and nitrates by some. However, if subjected to intensive plowing and thoroughly aerated, well-decomposed peats are usually rich in nitrogen. If it is desired to raise alkaline-soil crops and the acidity of the peat can not be corrected by plowing and aeration, lime should be applied.

Many peat areas in the northern or glacial region are underlain by beds of marl, a white or gray claylike variety of limestone composed largely of calcium carbonate ($CaCO_3$) brought into lakes and marshes by springs or stream waters and precipitated through the agency of blue-green algae and stoneworts (*Chara*). The plants extract carbon dioxide from the water and thus cause the deposition of the lime held in solution. Deposits of fresh-water marl are common in the southern peninsula of Michigan, in northern Indiana, in western New York, and in northwestern Pennsylvania. Shell limestone deposited by organisms is another common kind of calcareous material frequently found beneath peat in the coastal region. Dense, fine-grained limestone, marble, travertine, oolitic limestone, and chalk, though not commonly associated stratigraphically with peat, occur in many regions near peat deposits. There are, therefore, many peat areas in this country which on account of their acidity are of little value for general farming but which could be economically treated with lime from associated or adjacent deposits and made to yield large alkaline or neutral-soil crops.

Where it has been properly used the application of lime to peat soil has resulted in increased fertility. The limestone should be ground or burned before use as fertilizer, as the lime is then available immediately, whereas if applied in an untreated condition some varieties of limestone, notably shell "marl," are relatively inactive the first year. The chemical and physical effects of liming are manifold. It releases potash from certain silicates; it promotes the decomposition of the peat, freeing soluble nitrogen; applied to sour soils, it corrects the acidity; and applied to peat soils that harden in lump form upon drying, it renders them easily workable.

PEAT FUEL.

MACHINE PEAT.

The following data[1] based upon the experiments of the Canada department of mines show the cost of a machine peat-fuel plant and of producing air-dried machine peat in commercial quantity in

[1] Haanel, B. F., Peat, lignite, and coal: Canada Dept. Mines, Mines Branch, Pub. 299, p. 27, 1918.

Canada before the war. The cost of production was calculated from an output in five months of 3,300 short tons of fuel containing 25 per cent moisture.

Cost of 30-ton Anrep peat plant.

100 acres of peat land, at $6 an acre	$600.00
Peat machine, locomobile, tracks, cars, cables, etc	7,500.00
Blacksmith shop, office, loading platform, and railway siding	1,100.00
Drainage, clearing, etc	1,500.00
	10,700.00

Cost of producing a ton of air-dried machine peat.

Labor and supervision	$1.21
Repairs, fuel, oil, waste, etc	.15
Amortization and interest	.34
	1.70

PEAT BRIQUETS.

Peat briquets are usually made from raw peat that has been air dried to a moisture content of 40 per cent. After the peat has been macerated and powdered, the moisture is further reduced to about 15 per cent by artificial drying. A binder is then mixed with the peat and the mixture is compressed into cylindrical or prismatic shape by means of a piston subjected to a pressure of 18,000 to 30,000 pounds to the square inch.

Although there is a little more heating value per pound in peat briquets than in machine peat, the briquets are cleaner, more compact, greater in heating value per volume, and generally more attractive than machine peat. These advantages, however, are more than offset by the high cost of production. Artificial drying requires nearly as much heat as that obtainable from peat briquets prepared in this manner, and the cost of binders and compressing is so great that the process is of doubtful commercial value in the United States.

PEAT COKE AND CHARCOAL.

Peat charcoal was made in Europe for hundreds of years by piling cut peat in dome-shaped heaps, covering it with soil, and burning the peat with a restricted supply of oxygen. This process is little used now and peat charcoal has been displaced by peat coke, which is manufactured in Europe by the Ziegler process.[1] According to this method the coke is produced by heating machine peat blocks in specially designed retorts. Good peat coke is equal in quality to the best grades of charcoal produced from wood. If made from blocks of well-macerated, thoroughly decomposed peat that contains little ash, peat coke is compact and hard and should be able to compete with coke manufactured from coal. Alcohol, acetic acid, ammonia, ammonium sulphate, paraffin wax, illuminating and lubricating oil, phenol, and asphalt are some of the valuable by-products that may be obtained in coking peat by the dry distillation process.

Peat coke is extensively used in Europe, but in the United States, though it could probably be prepared for about $4 a ton, this material

[1] Nystrom, E., Peat and lignite, p. 176, Canada Dept. Mines, Mines Branch, 1908.

has never been commercially produced. There are large deposits of peat suitable for the production of coke within a few miles of the iron-mining districts of Minnesota, and it seems that the practicability of locating peat-coke plants in this regon should receve thoughtful consideration from engineers.

There are two kinds of by-product gas-producing plants that use peat—the Mond and the Frank-Caro.[1] The same principle is applied in both and the diffierences between them are minor. Crushed peat is fed into a furnace in which combustion is regulated by steam and hot air. The peat burns at the bottom of the feed shaft, and, reacting upon the steam, forms water gas and ammonia. These gases are next cleansed of tar by means of a scrubber and are subjected to a fine shower of sulphuric acid, which converts the ammonia into ammonium sulphate and purifies the water gas. After being cooled the water gas may be used under steam boilers, in internal-combustion engines, and for other purposes.

It is said that at Cordigoro, Italy, peat containing 2.5 per cent of combined nitrogen, when treated by the Mond process, yielded 170 pounds of ammonium sulphate to the ton. Gas-producing plants using peat fuel have been operated in England, Ireland, Germany, Sweden, Italy, and Russia, but not in the United States, although experiments have been made here. Analyses of the peats of the United States show that they are rich in combined nitrogen, from 70 to 85 per cent of which—a proportion that in some peats amounts to more than 2 per cent of their dry weight—could be recovered in the form of ammonium sulphate in by-product gas-producing plants.

OTHER USES.

PACKING MATERIAL.

Because of its lightness, resiliency, and antiseptic properties, peat makes excellent packing material and has long been used for packing eggs, fruit, vegetables, and fragile articles. Dry peat is a nonconductor of heat and hence is valuable in ice houses and as packing for water pipes. The best material is obtained from the fibrous types of peat consisting of partly disintegrated grasses and mosses. Peat moss is also utilized by florists and nurserymen in shipping flowers, shrubs, and plants.

PAPER, WOOD, AND CLOTH.

Peat was used a few years ago at a plant near Capac, Mich., for the manufacture of cardboard and paper. Grass and sedge peat would probably make the best paper stock, as this peat consists of strong fibrous material. It is understood that rugs are also made in this country from incipient sedge and grass peat. Peat has been successfully used in Europe for the manufacture of wall board and other artificial wood products. German and Swedish manufacturers have also made a durable yarn from a mixture of peat moss, shoddy, and wool, from which a cloth resembling cheviot is woven.

[1] U. S. Geol. Survey Bulls. 290 and 332 and Prof. Paper 48; Bur. Mines Bulls. 4, 7, 9, 13, and 16. Wyer, S. S., Producer-gas and gas producers, 1907. Haanel, B. F., Peat, lignite, and coal: Canada Dept. Mines, Mines Branch, Pub. 299.

MUD BATHS.

At certain health resorts in Germany and Austria peat has long been successfully used for so-called "mud baths," and during recent years experiments have been made to test the healing properties of peat in some of the sanitariums of this country. Well decomposed peat, free from coarse or woody material is the basis of the mixtures used, and it is reported that persons suffering from rheumatism and like diseases are materially benefited by the treatment.

PEAT INDUSTRY IN PRINCIPAL FOREIGN COUNTRIES.

GENERAL CONDITIONS.

The year 1918, as a result of the rather general shortage and high prices of coal, was one of great expansion and prosperity in the peat industry of most European countries. The quantity of peat produced and sold in some of these countries exceeded the quantity marketed in any preceding year. More peat fuel was produced than any other peat product, but the most interesting development was the world-wide use made of peat or sphagnum moss in the preparation of surgical dressings.

RUSSIA.[1]

Stimulated by war and the consequent shortage and high price of coal, the output of peat fuel in Russia in 1918, was approximately 10,000,000 metric tons, or almost double the quantity produced in years preceding the war. Of this quantity about 7,000,000 metric tons was manufactured in the central provinces. The sale of peat fuel machines, which affords a fairly reliable index to the ratio of increase in production, has more than doubled in recent years.

The Electrical Transmission Co., of Moscow, which annually supplies that city with approximately 40,000,000 kilowatt hours of electrical energy by the use of peat, recently applied to the Russian Government for a loan of 8,000,000 rubles to meet the high cost of labor occasioned by the war. It is understood that the minister of trade and industry recommended that the request be granted.

GERMANY.

Information concerning conditions in the peat industry of Germany has been difficult to obtain during the war, but the following data furnished by Sergt. H. E. Stanley, of the American army of occupation, and made available to the survey through the courtesy of the Fertile Chemical Co., of Cleveland, Ohio, indicate that the production of peat fuel in Germany has reached a high state of development:

Extensive peat beds, varying in depth from 1 to 17 meters, are found between Bruhl, Germany, and the Holland border. There are many plants near Bruhl and Liblau, where deep peat of good quality is found. About 35 peat-fuel plants are also located between Bruhl and Cologne and more than this number north of Cologne.

After the peat has been excavated, it is loaded in buckets, which are carried on aerial cables from the deposit to the plant, in some instances a distance of 2 kilometers. The raw material is run through a macerator, pressed into blocks,

[1] Am. Peat Soc. Jour., vol. 11, 2, pp. 50–53, 1918.

and stamped with the firm name. It is said that when the peat reaches the plant it contains about 80 per cent of moisture, which is reduced to 15 per cent by natural and artificial drying. As most of the work is done by machinery, little hand labor is required.

DENMARK.

Conditions in Denmark in recent years have been decidedly favorable to the expansion of the peat industry. The following table, based upon data furnished by John Olsen, of Arlington, Mass., shows the stimulating effect of the coal shortage during the war on the peat-fuel industry of Denmark:

Air-dried machine peat produced and consumed in Denmark, 1914–1918.

Year.	Number of producers.	Quantity (metric tons).	Average price per ton.	Value.
1914	65	86,849	(a)	(a)
1915	69	95,145	$4.08	$388,191
1916	160	118,484	6.43	761,852
1917	564	397,846	7.70	3,063,414
1918	1,380	851,546	7.00	b 5,960,822

a Not available. b Estimated.

There are two processes of producing machine peat in Denmark, the wet and the dry. According to the wet process, which is the one in most general use, water is added to the peat as it is put through the machine, and the resultant mudlike mixture is then spread out on drying fields and molded or cut into bricks by hand. This process, which originated in Denmark, produces a firm, dense brick particularly well adapted for industrial fuel. In the dry process the peat is macerated without the addition of water and cut by the machine into bricks, which are then spread out on the drying field.

Producers of hand-cut peat reported an output of 1,407,435 metric tons, estimated to be worth $9,039,178. A basic price of $7 a metric ton for peat having a combined ash and moisture content of 40 per cent was established in 1918. About 60 per cent of the machine peat produced in Denmark in 1918 was used for industrial purposes, and the cut peat was largely consumed in households. A series of tests was made with peat as locomotive fuel, and peat was used regularly on two branch lines with good results. The distances run during tests were from 45 to 85 miles, and the peat consumed amounted to 6.7 pounds per car-mile.

A textile industry in Denmark, based upon peat, seems to be a prospective result of experiments recently conducted in that country.[1] It is reported that a grayish material resembling woolen cloth is woven from yarn 75 per cent of which consists of peat fiber and 25 per cent of woolen waste. Knitting machines by which hosiery was made from peat yarn were shown in 1918 at an exhibition in Goteborg. A plant for the manufacture of peat yarn has been established at Silkeborg, and other factories will probably be erected. A new corporation, known as the Dansk Mose-Industri, with a capital stock of $34,840, was organized at Aarhus, Denmark, in 1918, for the production of peat products. A peat-briquet factory is also being erected at Brondersler.

[1] Commerce Repts., Oct. 9, 1918.

SWEDEN.

The output of machine-peat fuel in Sweden in 1917 was approximately 100,000 metric tons, compared with only 22,500 tons in 1916. These figures do not include hand-cut peat produced by peasants for local use, which probably amounts to more than the output of machine peat.

A large quantity of powdered peat was used in Sweden in 1918 for the generation of steam in locomotive boilers. A description of the type of locomotive adapted to use powdered peat for fuel and of the method of operation is given in a recent report to the Department of State by the United States Ambassador at Stockholm, Sweden.

Material progress was made in Sweden in 1918 toward the development of a peat cloth industry.[1] It is said that an economical method has been devised for extracting, carding, and spinning peat fiber. Plants were constructed at Hadenge, in Jonkoping Len, and at Goteborg for the manufacture of peat cloth from which matting, felt, carpet stuff, and even clothing may be made. The plants are reported to be capable of producing peat yarn at 4 cents a pound which can hardly be distinguished from wool.

It is reported[2] that mineral oil may be extracted from the peat deposits of Sweden and that there are good opportunities in that country of thus building up a domestic oil industry. Good air-dried Swedish peat yields, by dry distillation, from 5 to 8 per cent of tar, from which motor, illuminating, and lubricating oils, paraffin, and creosote may be extracted.

Many new companies for the production of peat were organized in Sweden in 1918, the largest of which is the South Swedish Peat Industry Union, capitalized at $1,000,000, and capable of producing 12,000 metric tons of peat annually. It is estimated that Sweden contains about 12,355,220 acres of peat.

BRITISH ISLES.

Peat in the form of crude hand-cut blocks has been the only fuel of many Irish peasants for centuries. It is estimated that Ireland contains 3,000,000 acres of peat land, a quantity sufficient to meet the needs of that country for a thousand years. Despite this vast reserve, peat fuel was scarce in Ireland in 1918, and the price rose in some parts of the country from $1.20 to $4 a horse load, or about $10 a short ton. There has been much discussion recently in Great Britain concerning the use of Irish peat as a source of fuel for the generation of electricity, and an experiment to demonstrate the potentialities of peat for this purpose was begun in 1918. It is believed that this is the most efficient use of peat that can be made, and that if peat fuel of better quality than that produced by the peasants for use in their own homes could be supplied at a low price the domestic welfare of the Irish people would be materially improved.

The following excerpt from a report[3] relating to the peat resources of the British Isles indicates that peat attracted wide attention in 1918:

---

[1] U. S. Commerce Repts., 163, p. 169, 1918.
[2] Berlingske Tidende, Copenhagen, Denmark, 1918.
[3] Sherman, H. T., Suggestions for coal substitutes: Consular Rept., Nov. 25, 1918.

The scarcity of coal in Great Britain caused by the lack of miners raised the question in 1918 of coal substitutes, and peat was mentioned as a prospective low-grade fuel.

The peat deposits of England, Scotland, and Wales have been almost untouched because of the abundance and low price of coal, but war conditions, necessitating the conservation of coal supplies, have directed attention to the larger utilization of peat for the generation of heat and power. According to the estimates of engineers who have studied the subject there are immense reserves of peat in the British Isles. The peat deposits of the United Kingdom are estimated to cover more than 6,000,000 acres and to contain material equivalent in heating value to 5,000,000,000 metric tons of anthracite coal.

Although peat fuel was not extensively used in England and Scotland in 1918, nearly 12,000,000 peat-moss pads were prepared and used in British military and naval hospitals in that year. Figures concerning the value of these pads are not available, but it is estimated that if absorbent cotton had been used exclusively in the hospitals the increased cost of antiseptic pads would have been about $200,000.

SWITZERLAND.

The shortage of coal in Switzerland in 1918 led to the use of peat as a source of gas. The Demolis process, by which the excessive carbon dioxide is converted into carbon monoxide in passing over wood charcoal, is used.

CANADA.

Conditions in the peat-fuel industry of Canada are like those in the United States. Although Canada has many large peat deposits, coal is the staple fuel, and little has been done to produce peat fuel commercially. The following excerpt[1] shows the efforts that have been made by the Canadian Government to stimulate the production of peat fuel:

Efforts have been made for many years to develop the peat deposits of Ontario and Quebec. Large sums of money have been spent by individuals and companies and yet there is little peat fuel produced commercially in Canada. About six years ago, however, the Government decided to make a practical investigation of peat production, and if possible to demonstrate the value of peat fuel. Representatives were sent to Russia, Germany, Holland, Denmark, and Sweden to collect data relating to peat-fuel production. When these agents returned 300 acres of peat land near Alfred, Ontario, was purchased and peat fuel was manufactured by the process which had been most economical in Europe. Approximately 2,000 short tons of peat was produced at a low cost and sold to householders and manufacturers, and it was reported by them that the peat proved to be satisfactory fuel. After this successful demonstration the Government believed that its work had been accomplished and that further development should be left to private interests. Accordingly the plant was sold, but the buyers were undercapitalized and further handicapped by the outbreak of the war, and consequently the plant ceased to operate.

In the spring of 1918, owing to the fuel shortage occasioned by the war, attention was again directed to the peat deposits and money was appropriated by the Federal Government and the provincial government of Ontario for a further demonstration of peat-fuel production. A peat committee was named, and Ernest V. Moore, of Montreal, was selected as engineer to conduct the experiments. The erection of two plants was begun, one of which was modeled after the Alfred plant mentioned and the other was a new design calculated to meet the slight defects of the former. It is understood that both machines will excavate, macerate, and spread out the peat for air drying as they move over the

surface of the bog. At the close of 1918 the plants were not completed, but it is said that they will be operating at their full capacity of 6 tons each per hour during the summer of 1919.

Peat fuel produced in Canada, 1900–1916.

URUGUAY.

It is reported[1] that rights to develop peat deposits near Maldonado, Uruguay, were acquired in November, 1917, by the Sociedad Anónima Turberas Carboníferas de Maldonado, and that since then dried peat at the rate of 20,000 metric tons a month has been produced at times, although this rate of production has not been continuously maintained for more than a few days.

PRODUCERS OF PEAT IN THE UNITED STATES.

The following individuals and companies reported to the Geological Survey that they produced crude peat or peat products in the United States in 1918:

Alphano Humus Co., Whitehall Building, New York, N. Y.
American Peat Products Co., Morrison, Ill.
Atlantic Humus Co., Newbern, N. C.
Chapman, I. S., & Co. (Inc.), 937 Third Street, San Bernardino, Calif.
Cole, Norvin G., Hopewell Junction, N. Y.
Commercial Humus Co., 503 Firemen's Building, Newark, N. J.
Day, James H., 35 South Street, Milford, N. H.
Espy Humus Fertilizer Co., Espy, Pa.
Fallows, F. H., Auburn, Maine.
Hall, George W., North Adams, Mass.
Humus Natural Manure Co., 1964 Broadway, Brooklyn, N. Y.
Hyper-Humus Co., Newton, N. J.
McElhone, Asa, Fishkill, N. Y.
New Era Development Co., 110 State Street, Boston, Mass.
Orchid Humus Fertilizer Co., 743 Frost Avenue, Peekskill, N. Y.
Pierson, A. N. (Inc.), Cromwell, Conn.
Riverside Orange Co. (Ltd.), Arlington Heights, Riverside, Calif.
St. Joseph Humus Co., Van Wert, Ohio.
Sims, Alfred F., Sag Harbor, N. Y.
Southern Humus Co., Smyrna, Ga.
Tifton Guano Co., Tifton, Ga.
Upton, Roger, Marblehead, Mass.
Virginia-Carolina Chemical Co., Richmond, Va.
Wiedmer Chemical Co., Pierce Building, St. Louis, Mo.

SULPHUR AND PYRITES.[1]

By Philip S. Smith.

WAR MEASURES.

The entrance of the United States into the World War necessitated a careful inventory of the country's mineral resources and the formulation of definite policies as to their proper war use. It soon became apparent that sulphur or minerals from which sulphur could be obtained were vitally necessary in the war program of the Nation for the manufacture of munitions and for the fertilizers that would augment the production of crops requisite to furnish the food and clothing that were indispensable to the successful prosecution of the war.

The principal materials used as sources of sulphur are native sulphur and pyrites. Crude native sulphur—sulphur as it comes from the ground—may contain impurities in large quantities. In the United States, however, more than 99 per cent of the native sulphur produced is mined by melting it with hot water in the rocks in which it occurs below the surface and forcing the hot liquid sulphur to the surface. Most of the sulphur produced by this method of mining is very nearly pure. In current commercial practice this sulphur is guaranteed to be 99.5 per cent pure, so that the domestic crude sulphur really contains almost no visible impurities.

Pyrites is a general trade name for a number of different sulphur-bearing minerals or sulphides. The two most common minerals are pyrite and marcasite, disulphides of iron (FeS_2), which when pure contain about 53 per cent of sulphur and 47 per cent of iron. These two minerals differ from each other principally in their mode of crystallization; pyrite usually forms cubes, whereas marcasite forms tabular crystals. Pyrrhotite (Fe_7S_8), is also called pyrites. Pure pyrrhotite contains about 40 per cent of sulphur and 60 per cent of iron.

The sulphur-bearing minerals named differ in the proportion of sulphur they yield and in the manner in which they are treated. For instance, pure native sulphur burns in the flame of a match and is entirely consumed; pyrite or marcasite may be ignited by a match but is soon extinguished, and even when all the sulphur is consumed it leaves behind a mass of iron oxide nearly as large as the original piece of pyrite; pyrrhotite will not easily ignite, yields much less sulphur, and leaves a still larger residue than either pyrite or marcasite.

[1] The statistics in this report were compiled by Mrs. Agnes L. Sullivan, of the United States Geological Survey.

In addition to these minerals that are primarily used for their sulphur content many ores of the metals, such as those of copper, lead, and zinc, contain enough sulphur to make the utilization of their sulphur as a by-product commercially profitable. Although all these materials will yield sulphur-bearing gases the question whether they shall be used is determined largely by cost and dependability of supply. As native sulphur contains twice as much sulphur as pyrites or any other sulphur-bearing ore, if the charges for transportation are the same for all kinds, the actual charge against the sulphur in a ton of native sulphur is but half that borne by the sulphur in a ton of pyrites. Furthermore, only half a ton of sulphur need be burned to give the same volume of gas as a ton of pyrites so that less labor is required to feed it to the burners, not nearly as much residue is produced, and less labor also is required for cleaning the burners for a new charge. On the other hand, the great producing sulphur mines, near the northeast coast of Texas and the southwest coast of Louisiana, are more distant from sulphur-consuming centers of the country than are some of the deposits of pyrites.

The records of the Survey regarding sulphur materials, which have been maintained for nearly 40 years, show that in the years immediately preceding the war about 300,000 long tons of crude sulphur, 1,500,000 long tons of pyrites, and more than 1,000,000 short tons of sulphur-bearing ores of copper and zinc were produced or used for their sulphur content in the United States each year. The quantity of crude sulphur produced was so large that in 1913 about 90,000 tons were exported and about 15,000 tons were imported. This country was therefore self-sufficient, so far as its usual demands for native sulphur were concerned. The outlook for an adequate production of domestic pyrites was not so favorable. Although enormous deposits of pyrites occur in the United States, many of them are not near the places where the material is used, could not quickly be made to yield large quantities, and could not be worked in competition with deposits mined with cheap labor. As a consequence the domestic production of pyrites before the war was about 350,000 tons a year and the importation of pyrites, mainly from Spain, was nearly 1,000,000 tons a year.

The foregoing facts make it evident that many diverse interests were involved in the proper solution of the problems that arose concerning the use of sulphur materials in the many different activities of war and industry. The fundamental requirements, however, were the determination of the sulphur and pyrites resources of the country and the collection of accurate statistics of the quantity produced. These requirements had long been met by the work of the Geological Survey, which merely continued the work, but pursued it more intensively and expeditiously. Thus, instead of compiling statistics of production annually it obtained returns from all producers each month, and the figures were made available to all the war organizations of the Government through the courtesy of the producers, who released their confidential records for all Government uses. Field examinations to determine available reserves and to keep a check on the data showing production were made whenever and wherever special information was required.

In addition to knowing the quantity of sulphur available, the location of the deposits, and the normal and current rate of production, it was necessary to know how much could be mined during different periods and how the deposits could be developed more expeditiously and more economically. There were also problems of transportation involving the moving of large quantities of ore without interfering with more urgent war needs and without using ships for importing foreign pyrites. There was also the very important problem of determining the quantity of sulphur material required for the war program as laid down by the Government—a program which was in a constant state of rearrangement owing to the need of balancing the demand for supplies against the producers' ability to furnish them. Then, too, there was the need of definite decisions as to the relative importance of all commodities, so that with a wide outlook encouragement or curtailment of any activity should be wisely applied and administered. These matters were handled by many different Government organizations and often the conclusions reached by one were not accepted by others, so that for a time there was a great deal of lost motion, misdirected activity, and absence of a clearly announced policy to be rigorously followed.

One of the earliest of the new organizations that among other things concerned itself with the sulphur and pyrites industry was the subcommittee on fertilizers of the Committee on Chemicals of the Advisory Committee of the Council of National Defense. This committee served for some time as an adviser, but it had little actual authority to compel acceptance of its decisions. In the later part of 1917 the Chemical Alliance was formed as an organization of the users and producers of various materials including sulphur and pyrites. Near the end of 1917 and in the beginning of 1918, most of the advisory boards were dissolved and the Chemical Alliance took over the work formerly done by the Committee on Chemicals. One section of the alliance was devoted to domestic pyrites and sulphur and another section to foreign pyrites.

The end of 1917 and the beginning of 1918 marked the establishment of several of the larger and more powerful Government war organizations, such as the War Trade, War Industries, and Shipping boards. The severe winter, which badly hampered the movement of commodities by rail, resulted in placing local embargoes on many commodities and later this resulted in forcing a decision as to the relative value or importance of the various articles in the war so that priority of transportation might be granted to them in the order of their importance. In February priorities were granted by the car-service section of the Division of Transportation of the United States Railroad Administration to pyrites and fertilizer materials in section G, class 2. The President's proclamation of February 26, 1918, effective March 20, 1918, under the authority conferred by the food-control act of August 10, 1917, put the fertilizer industry under license system. Pyrites, sulphur, and sulphuric acid, as well as the other fertilizer ingredients came under the provisions of this proclamation and licenses for these commodities were handled by the License Division of the United States Food Administration. Licenses, however, were not required for dealers whose gross sales amounted annually to less than $100,000.

The serious inroads on shipping by the enemy's submarines and the need of all available ships for the transportation of troops and munitions resulted, late in January, 1918, in representation to the War Trade Board and the Shipping Board that the importation of Spanish pyrites could be considerably curtailed. Finally, in March, an agreement between the Government, the producers, and the consumers was reached, whereby licenses for only 125,000 tons of pyrites imported from overseas would be granted between April 1 and October 1. This quantity was only about a quarter of the usual imports from overseas in the same months of other years. This curtailment was to be put into effect gradually, so as to permit all necessary business adjustments, and the imports were to decrease from 40,000 tons in April to 10,000 tons in August and September. Not all of even this greatly decreased quantity of foreign ore was actually imported.

The withdrawal of large bodies of men under the draft began to be seriously felt by the pyrites industry in the beginning of 1918, and by March many of the pyrites properties in the eastern United States were showing an actual falling off in production. Various governmental agencies, notably the Department of Labor, took steps to remedy the general shortage of labor, but the pyrites mines continued to find it impossible to get or keep men in competition with the great constructional operations of the Government, which paid higher wages and were believed by many to give greater immunity from active military service. Failure to mine as much pyrites as might have been produced was caused by lack of labor, as is shown by the fact that 12 mines, which together reported a capacity of about 530,000 long tons a year, produced less than 240,000 tons in 1918 and stated that a loss of more than 175,000 tons for the year was due to shortage of labor.

In July the greatly increased demand for sulphur and sulphur ores by the Government, as well as by private concerns, and the difficulty of properly distributing the supplies on the overburdened railroads and in the few ships that were available caused the War Industries Board to assume control of the production and distribution of sulphur materials. In taking over this control the board acted through the commodity chief in charge of pyrites and sulphur. This officer was permitted to avail himself of any voluntary assistance he desired from consumers and producers but he was instructed that "in case any producer or consumer declines to abide by the decisions of the War Industries Board, commandeering orders will be issued when necessary." This officer accepted the cooperation of the committee on production, distribution, and control of sulphur-bearing materials of the Chemical Alliance, and thus brought closely together the Government, the producer, and the consumer in a relation that continued during the remainder of the war. Soon after the signing of the armistice the war boards began discontinuing their work, licenses and restrictions were gradually removed, and the industries made all efforts to get back to normal conditions.

Late in 1917 and early in 1918 it was found that the production of many of the minerals needed was not so great as was desired, and moves were made to stimulate their production. One of these moves was the introduction in Congress of bills authorizing the appointment of a mineral administrator. Hearings on these bills, at which the Government agencies, the producers, and the consumers ap-

peared, were held throughout March, April, and May, and after various changes in the scope of the proposed legislation a bill was passed October 5, 1918, and the administration of the act was placed in charge of the Secretary of the Interior. As the armistice was signed in November, 1918, this legislation was too late to be of much benefit, because the problem had suddenly changed from one of stimulating production to one of absorbing the overproduction resulting from the close of hostilities. Many of the producers had undertaken to develop mineral properties at the urgent appeal of the Government for adequate supplies of needed mineral commodities, and some of them found that their markets were taken away and that they were facing substantial financial loss. After much discussion the conclusion was reached that reimbursement of claims of this sort was not authorized by the terms of the legislation that had already been enacted. The good faith of the Government, however, was involved in the stimulation of certain of the enterprises, and another bill to cover these cases was presented to Congress. This bill, which was passed and became effective March 3, 1919, permitted reimbursement for losses sustained by producers of certain minerals on presentation of satisfactory evidence that they had undertaken their enterprises in good faith through representations made by responsible Government officials. This act is administered by the War Minerals Relief Commission, which serves under the Secretary of the Interior. The only minerals coming under the provisions of this act are manganese, chromite, tungsten, and pyrites, and the only losses from which relief is provided are those incurred subsequent to April 6, 1917, and prior to November 12, 1918, and all claims were required to be in the hands of the commission within three months of the passage of the act.

SULPHUR.

DOMESTIC PRODUCTION.

Sulphur was reported to have been produced in 1918 by nine mines—one each in Louisiana, Wyoming, Colorado, and California, two in Nevada, and three in Texas. The two largest producers of sulphur are the Union Sulphur Co., whose mine is at Sulphur, Calcasieu Parish, La., and the Freeport Sulphur Co., whose mine is near Freeport, Brazoria County, Tex. These two companies continue to furnish about 99 per cent of the sulphur produced in the United States.

Two properties that had not been in operation in 1917 reported a small production in 1918. One of these properties is in Colusa County, Calif., and the other is in Culberson County, Tex. A mine in Park County, Wyo., that produced sulphur in 1917 was idle in 1918. The quantity of sulphur produced by the new mines was, however, less than that formerly produced by the Wyoming mine that was idle in 1918, so that stimulation through national need and war prices did not increase the production of the smaller companies. The two large mines, however, responded amply to the demand for more sulphur than ever before and fully lived up to their promise to meet the country's need; and these two mines met the call for sulphur without having to reduce their stocks—in fact, larger stocks of sulphur were on hand at the end than at the beginning of the

year. The large immediately available supply represented by the stocks on hand was a constant insurance against any curtailment of the military program through shortage of sulphur. The value of this protection was especially evident in August, when a cyclone razed practically all the equipment above ground at the Union Sulphur Co.'s mine and stopped all production there for several days. In spite of this handicap, however, shipments were continued at almost the same monthly rate as during the preceding months. At no time did the company relax its efforts to produce sulphur and resort to drawing on its stocks. As a consequence, the damage done by the storm was remedied as quickly as possible and new construction was rushed so fast that, although the storm occurred August 5, the production from the mine for October was far above its monthly average for the year and was only a few hundred tons less than the greatest quantity produced in any month of the year.

Through the courtesy of the sulphur producers it is possible to publish statistics of the sulphur industry in the United States for the last 10 years. The information for 1915, 1916, and 1917 has not heretofore been published.

Sulphur produced and shipped in the United States, 1909–1918.[a]

Year.	Mined.	Shipped.		Year.	Mined.	Shipped.	
	Quantity (long tons).	Quantity (long tons).	Approximate value.		Quantity (long tons).	Quantity (long tons).	Approximate value.
1909	273,983	258,203	$4,782,000	1914	417,690	341,985	$6,214,000

[a] Revised figures.

The effect of the war on the production of sulphur as well as the changes in the importance of the industry is perhaps best shown by the graphic representation of the production from 1880 to 1918 in figure 60 (p. 363).

The statistics in this report are somewhat different from those formerly published by the Geological Survey, as certain records that have not heretofore been available and that proved to be more accurate than those used have been placed at the disposal of the Survey. This diagram shows that from 1880 to 1901 the sulphur produced in the United States was less than 8,000 long tons a year and for eight of those years was less than 1,000 tons a year. From 1902 to 1906 there was a great increase in production, which in 1906 reached almost 300,000 tons. From 1906 to 1916 the production fluctuated within rather wide limits, and averaged about 400,000 tons a year. In 1917 the production (1,100,000 tons) was nearly double the great output of 1916, but even that high mark was exceeded by more than 200,000 tons in 1918. The production for 1918 doubtless marks a limit that will not be reached again in many years.

Statistics of the production of sulphur by the rest of the world in 1918 are not yet available, but the output in the United States alone in 1918 was 65 per cent more than the total output of the world in 1913. In 1913 Italy and the United States produced almost the same quantity of sulphur, but since that year the production from Italy has decreased, so that the relative standing of the two countries is now very different. The only other country which made a large output of sulphur was Japan, and in 1913 that country produced only 8 per cent

of the world's sulphur. So far as has been learned the sulphur industry of Japan has not increased to any marked extent during the last three years; in fact, it is commonly reported that in spite of the greatly increased manufacture of sulphuric acid in that kingdom, its output of sulphur has been falling off.

IMPORTS.

The quantity of foreign crude sulphur imported into the United States in 1918 was insignificant, amounting to only 55 tons. The need of restricting the use of shipping to transporting only the most essential war materials doubtless helped to decrease the imports, but probably a more effective cause of the decrease was that many of our Allies used sulphur from Italy and other foreign deposits for their own war needs. Inasmuch as the domestic supply of sulphur was

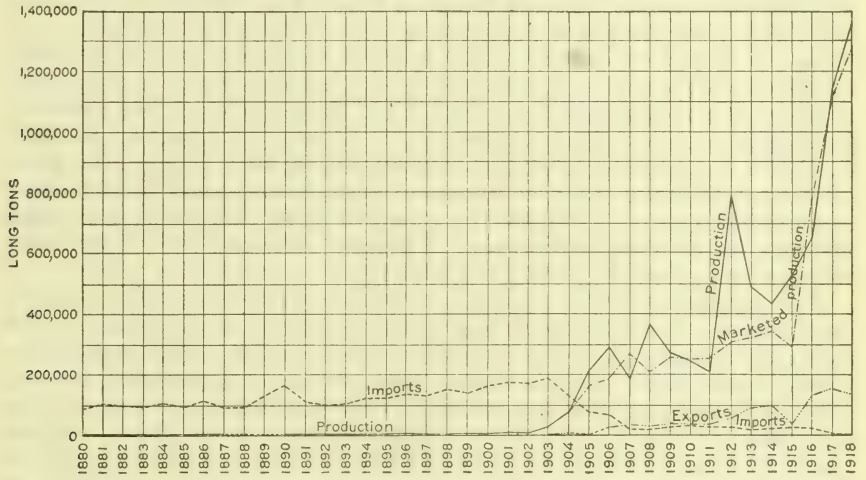

FIGURE 60.—Domestic production, imports, and exports of sulphur, 1880–1918.

adequate for the United States, much unnecessary cross haul was thus avoided.

The data in the following table were furnished by the Bureau of Foreign and Domestic Commerce.

Crude sulphur imported into the United States in 1918.

Country.	Port of entry.	Quantity (long tons).	Value.
Japan	Washington State	50	
	Hawaii	1	
Mexico	New York City	4	
		55	$1,692

The total value ($1,692) of the crude sulphur imported in 1918 was equivalent to about $31 a ton, or about $10 a ton higher than in 1917. In addition to the crude sulphur, about 27 tons of lac or precipitated sulphur, valued at $7,850, was imported in 1918 by the United States.

The imports of sulphur by the United States from 1880 to 1918, inclusive, are presented in figure 60, which shows that from 1880 to 1903 the annual imports averaged not less than 100,000 long tons. The minimum quantity imported was 87,837 tons in 1880, and the maximum was 188,990 tons in 1903. In the period of rapid increase in the domestic production from an average of 8,000 tons in 1901 to almost 300,000 tons in 1906 the demand for foreign sulphur began to lessen, and the imports decreased to about 20,000 tons. Since 1907 the imports have never exceeded 30,000 tons a year and have averaged about 20,000 tons. The smallest quantity imported in any year (55 tons) was in 1918.

EXPORTS.

The sulphur exported in 1918, according to the Bureau of Foreign and Domestic Commerce, amounted to 131,092 long tons, valued at $3,626,638, or an average of $27.66 a ton. This quantity was about 20,000 tons less than was exported in 1917, but was greater than that exported in any other year. The relation of the quantity of sulphur produced, exported, and imported is graphically shown in figure 60. Sulphur was first exported by the United States in 1904. In 1907, for the first time, the exports exceeded the imports. From 1906 to 1911, inclusive, the exports averaged roughly 30,000 tons a year. In 1912, 1913, and 1914 the exports increased successively, until in 1914 they amounted to nearly 100,000 tons, but in 1915 there was a decided decrease to less than 40,000 tons. This was followed by the enormous increase in exports in 1916, 1917, and 1918.

The greatest quantity of sulphur exported in any single month in 1918 was in February and was somewhat over 15,000 tons. From February to May, and again in November, the monthly export was about 14,000 tons. In January, from July to September, and in December the exports averaged from 6,000 to 8,000 tons, and in June and October about 11,000 tons. The following table shows the exports of crude sulphur from the United States to different parts of the world in 1918 and the customs districts from which it was cleared. Although the customs districts are distributed around the entire border of the country, practically all the sulphur exported was produced by the two large mines in Louisiana and Texas.

Sulphur exported from the United States in 1918, in long tons.

Destination.	Ports of clearance.						
	New York City.	Maine, New Hampshire, Massachusetts, and Vermont.	St. Lawrence, Buffalo, and Michigan.	Dakota, Duluth, Montana, Idaho, and Washington.	California and Arizona.	Texas and Louisiana.	Total.
North America	825	7,710	79,447	12,715	290	6,280	107,267
South America	3,092	.....	.....	.....	33	120	3,245
Europe	4,343	.....	.....	.....	.....	13,996	18,339
Asia	26	.....	.....	2	343	.....	371
Africa	470	.....	.....	.....	.....	1,400	1,870
	8,756	7,710	79,447	12,717	666	21,796	131,092

The exports of sulphur from the United States to different countries in the five years from 1914 to 1918, inclusive, are shown diagrammatically in figure 61.

There was a decrease in 1918 in the exports of sulphur to all the countries except those in North America. Of the 107,267 tons exported to North American countries, 99,927 tons were sent to Canada, 2,519 tons to Mexico, and 4,333 tons to Cuba. Of the 18,339 tons exported to European countries, 7,146 tons were sent to England, 4,850 tons to France, 4,253 tons to Portugal, and 2,000 tons to Norway; of the 3,245 tons exported to South American countries, 2,326 tons were sent to Brazil and 553 tons to Argentina; of the 1,870 tons exported to Africa, 1,676 tons were sent to British South Africa; and of the 371 tons of sulphur credited as exported to Asia, 341 tons were sent to Australia.

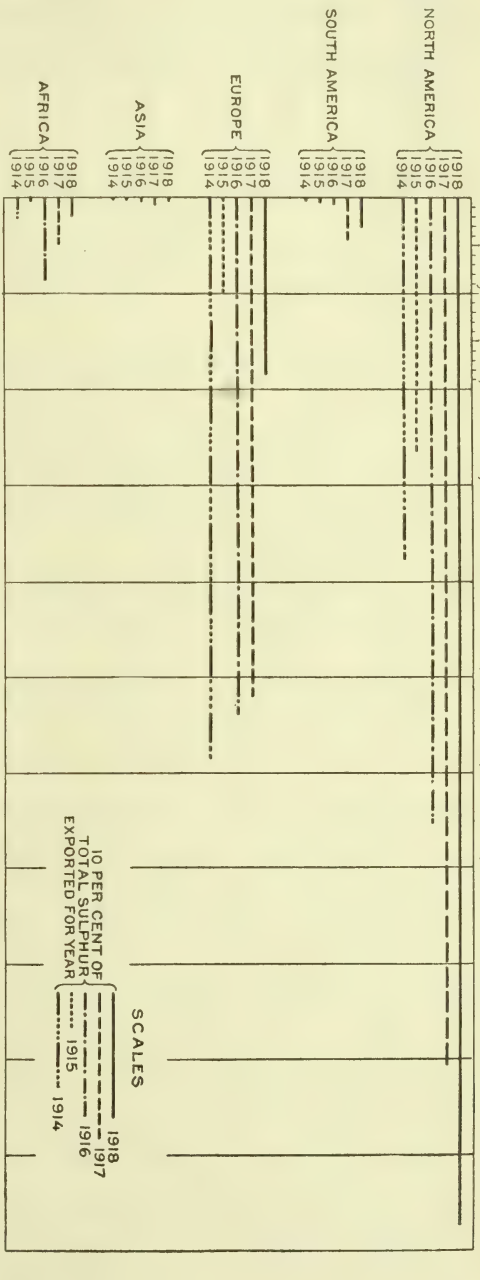

FIGURE 61.—Sulphur exported from the United States, 1914–1918.

CHARACTER OF DOMESTIC DEPOSITS.

At both the large mines the sulphur occurs under essentially similar conditions. From the surface to a depth of several hundred feet are unconsolidated sands and muds. Beneath the unconsolidated deposits is a limestone in places as much as 100 feet thick, locally known as the cap rock, because it covers the sulphur deposits. Next beneath the cap rock is limestone with some gypsum and large quantities of sulphur. Lower down the proportion of the limestone decreases, and in the next few hundred feet the beds are mainly

gypsum, with some sulphur and a little limestone. Still lower down the rock is massive gypsum. This gypsum member is said to rest on beds of salt of unknown thickness. The rocks below the unconsolidated deposits are apparently folded so that the rock surface forms a dome. In fact, the slopes of the sides of the rock dome are in places more than 45°. The sulphur does not occur in massive beds but in stringers and lenses, which traverse the adjacent rocks irregularly.

The early attempts to mine the Louisiana deposit, which was the first to be discovered, were unsuccessful until the double problem of reaching the deposit and of extracting the sulphur was solved by Dr. Herman Frasch. The original Frasch patents having expired, the same general process is now being used both at the original locality and at Freeport, Tex. Briefly this process is as follows: Holes nearly a foot in diameter are bored to the deposit by rigs and drills similar to those used in boring for oil, and the sulphur, which liquefies at about 116° C., is melted by the introduction of superheated water. After the sulphur has melted and collected at the bottom of the hole, it is raised to the surface by the use of compressed air. The sulphur in the liquid state is piped to large bins, where on cooling it consolidates. The solid sulphur in the bins is blasted down by powder, picked up by steam shovels, and loaded into box cars for railroad shipment or on open gondola cars for transportation to the loading dock for ocean shipment.

The sulphur obtained is not further refined at the mines, but is sold with the guaranty that it is at least 99.5 per cent pure. It contains no arsenic or selenium. Usually not all the sulphur in the adjacent rocks is melted out by one well, and consequently the practice has been to abandon a well after a certain length of time and later to go back to the same general place and sink another well. The distance to which the steaming affects the rock varies greatly according to local conditions. In some places wells less than 50 feet apart show no interrelation, whereas in other places wells more than 1,000 feet apart show distinct intercommunication. Already several hundred wells have been sunk at each mine, but of these only four or five yield sulphur at a time. The number of wells in operation at a time is limited not only by the equipment required to furnish the necessary hot water but also by the necessity of avoiding the setting up of excessive pressures underground. The quantity of sulphur derived from individual wells differs considerably. The most productive wells are said to have yielded more than 100,000 tons of sulphur.

According to recently published statements by the Trade Commission[1] regarding the cost of producing sulphur at the two large sulphur mines, "the cost of the Freeport Co. in 1917 was $6.15 per ton; in 1918 it is estimated that increases will bring the cost up to not over $9.50 per ton. In the first part of 1917 the Union Co.'s costs were $5.73 per ton."

At all the other producing sulphur deposits the sulphur occurs in part at least at the surface and is mined by stripping or by subsurface drifting. The ore is then taken to retorts or furnaces, where it is heated so that the sulphur liquefies and runs out of the rock. The sulphur usually constitutes from 10 to 50 per cent of the ore,

[1] Official Bull., vol. 2, No. 348, p. 13, 1918.

and although the ore can be mined at these places rather cheaply, the handling and further treatment required to free the sulphur from the worthless material is expensive. Furthermore, a good deal of the sulphur is not extracted by this rather crude method of treatment, and hence the difference between the original sulphur content of the ore and the quantity of sulphur recovered in practice is often very great.

Most of the companies producing small quantities of sulphur are developing localized deposits that seem to be more or less intimately connected with the dying out of volcanism or solfataric action. The richer parts of the deposit on a single property are therefore rather irregularly distributed and usually cover only a small area. The sulphur content is usually greatest in the surface portions, although in places the sulphur-bearing formation is reported to be as much as 40 feet thick.

SULPHUR DEPOSITS RECENTLY INVESTIGATED BY GEOLOGICAL SURVEY.

In the chapter on sulphur in Mineral Resources for 1916 all the known deposits of sulphur in the United States were described. In the similar chapter for 1917, a few additional sulphur localities were listed, among others one near Jemez Hot Springs, in New Mexico. Practically nothing was known regarding the value of this deposit as a source of sulphur, and accordingly Geologist George R. Mansfield was detailed to make an investigation of it. His report, which has already appeared in several of the technical papers, follows:

NEW MEXICO.

SULPHUR IN JEMEZ CANYON, SANDOVAL COUNTY.

By George R. Mansfield.

Small deposits of sulphur have long been locally known in Jemez Canyon, Sandoval County, N. Mex. Early in 1918 the suggestion was made that these deposits might be a source of commercial sulphur. Reconnaissance reports already available at the United States Geological Survey indicated that the deposits were probably of slight extent or value, but in order to obtain more detailed information a geologist was sent from the Survey to examine them. The examination confirmed the unfavorable reconnaissance report and showed that the deposits are not of commercial value.

The deposits occur at two places, one in the Canyon de San Diego grant, about 5 miles above Jemez Springs, nearly three-fourths of a mile below the forks of the creek; the other at Sulphur Springs, in the Baca location, about 14 miles above Jemez Springs. Inquiries at Jemez Springs elicited no information concerning any other deposits in the region comparable with these two. The nearest railroad points are Bernalillo and Albuquerque, on the Atchison, Topeka & Santa Fe Railway, about 45 and 60 miles, respectively, south of Jemez Springs, by the wagon road. The road for much of the way is heavy with sand.

San Diego deposit.—The sulphur ore at the deposit, which may be called the San Diego deposit, consists apparently of residual material

from Carboniferous limestone leached by acidulated waters and permeated by sulphurous vapors, which have deposited free sulphur in the crevices and pores of the upper few feet of rock.

The sulphur-bearing mass is about 700 feet long and 150 feet wide, occupying a lenticular area of about 1 acre. Two smaller areas, 50 feet or less in diameter, were noted in branches of a small tributary canyon about three-fourths of a mile to the northwest. The writer spent nearly three days in mapping, exploring, and sampling this deposit in association with Linus Shields, superintendent of the Canyon de San Diego grant. In this exploration, six prospect cuts were dug, exposing fresh sections ranging in depth from 2 feet 1 inch to 13 feet 6 inches. From these cuts numerous measurements were made and 11 samples were obtained for analysis. The sulphur is irregularly deposited and is in a relatively thin deposit, measuring only 2 feet 4 inches to 3 feet 4 inches in thickness in four cuts in the more promising parts of the area. In one cut the deposit was not penetrated at a depth of 4 feet 2 inches. The sulphur ore contains from 15 to 39 per cent of free sulphur and from 6 to 8.5 per cent of sulphur combined as sulphate. The rock under the ore contains no free sulphur, but about the same percentage of sulphur combined as sulphate.

Deposit at Sulphur Springs.—The deposit at Sulphur Springs is similar, except that it occurs in rhyolite, a volcanic rock. The rocks at this locality are at some places still warm to the touch, and there are numerous vents in them from which hot acidulated waters and sulphurous vapors are now being emitted. Some of these vents are being utilized for the hot water and vapor baths that make Sulphur Springs a local health resort. The escaping vapors have deposited sulphur on the walls of the vents, lining them with beautiful acicular or stout yellow crystals.

One day was spent in the trip to Sulphur Springs, where the deposit occupies about 9 acres in a small basin eroded in the rhyolite. A number of low slopes between drainage lines are covered with white débris and some yellowish spots suggesting sulphur ore, the presence of which was confirmed by making small pits, but pits in other areas disclosed no sulphur.

Sixteen years ago M. S. Otero, former Delegate to Congress from New Mexico, built at Sulphur Springs a mill equipped with a boiler, engine, pump, and two retorts of about 1-ton capacity each, for producing sulphur. The retorts were filled with ore and steam under pressure of about 30 pounds was led into them and the melted sulphur was drawn off below. On the death of Mr. Otero, two years later, the mill was closed and the property passed into the hands of his sons. According to A. T. Otero, who furnished the above data regarding development, the ore treated ran about 60 per cent sulphur and the total production amounted to about 200,000 pounds, of which 150,000 pounds were sold at Albuquerque, the rest being sold in small lots to local purchasers.

The ore used by the mill had been taken from an entry, now caved, on a low ridge that forms the southeastern extension of the deposit. A shallow cut, 4 feet 10 inches long, made on the side of this tunnel, showed seams of good sulphur in cracks, but the material as a whole did not run so well and seemed poorer toward the bottom. The crushed and quartered sample representing the entire

cut contained 31.85 per cent of free sulphur and 2.09 per cent of sulphur combined as sulphates.

All the sulphur at Sulphur Springs was apparently deposited in vents, cracks, and pores within a few feet or a few inches of the surface. The available sulphur in this area is apparently not large in quantity and is irregularly distributed.

About 2 miles above Sulphur Springs and at several places in Jemez Canyon between Sulphur Springs and the San Diego deposit, hot springs or leached rocks indicate similarly active waters and vapors on a smaller scale. Hot sulphureted water occurs at Jemez Springs. These phenomena occur in a zone more than 15 miles in length along the general line of Jemez Canyon, and suggest the occurrence of a deep fracture or group of fractures in the earth's crust along which acidulated waters and sulphurous vapors have risen here and there and deposited sulphur. No evidence was obtained that the deposits are connected with one another.

Conclusions.—The examination led to the following conclusions: (1) The deposits are local and were formed independently along one or more deep fractures in the earth's crust; (2) the San Diego deposit covers about 1 acre, and the Sulphur Springs deposit covers 9 acres, though it includes numerous barren areas; (3) the sulphur ore is irregularly distributed and is relatively thin, being only 2 feet 4 inches thick at four measured cuts; (4) the quantity of available sulphur is too small to be of commercial importance, especially in view of the inaccessibility of the deposits.

ALASKA.

Deposits of sulphur have long been known in the vicinity of several of the volcanoes of the Aleutian Islands and the Alaska Peninsula. Several of these deposits were noted in the chapter on sulphur in Mineral Resources for 1916. During the summer of 1917 the deposits on Unalaska and Akun islands and near Stepovak Bay, Alaska Peninsula, were visited by A. G. Maddren, of the United States Geological Survey. A complete report[1] of his observations has been prepared, but the following summary is quoted from a preliminary announcement of the investigation and its results.[2]

> The examination showed that although there is some sulphur at each place examined there is little probability that any of the deposits can be profitably mined at present or in the immediate future, for they are not of large area, most of them are probably shallow and contain only disseminated sulphur, supplies and labor are not obtainable near the deposits, the open season is short, the work of transporting the sulphur from the mines to the ships would be difficult, and the haul to the larger markets would be long. However, these deposits form part of America's sulphur reserves, and similar deposits undoubtedly occur at many other places in the volcanic belt of southwestern Alaska. When material and labor are more easily and cheaply obtainable, when transportation is cheaper, and when the demand for sulphur on the Pacific coast is larger, the sulphur deposits in Alaska can doubtless be mined profitably. The area within which workable deposits of sulphur may be found in Alaska is large and most of it is unexplored, so the place at which sulphur can be first and most profitably mined is not certainly known.
>
> Sulphur claims have been staked on deposits in the crater of Makushin Volcano, on Unalaska Island; on Akun Island; and near Stepovak Bay. No sul-

[2] U. S. Geol. Survey (unsigned), Sulphur deposits of Alaska: U. S. Geol. Survey Press Bull. 372, July, 1918.

phur has yet been marketed from these deposits, but during the last year they have attracted the attention of prospective investors with a view to their exploitation. Unalaska and Akun Islands are near the east end of the Aleutian Islands, in latitude 54° N., longitude 166° W., about 1,750 miles from Puget Sound. Stepovak Bay is on the south coast of Alaska Peninsula, in latitude 55° 50′ N., longitude 159° 40′ W., about 1,600 miles from Puget Sound.

The sulphur deposit at Makushin Volcano is about 12 miles west of Dutch Harbor, or 5 or 6 miles north of Makushin Bay. It is about 5,500 feet above sea level, in the only part of the crater that appears to be perfectly bare of snow and ice. This bare area covers 20 to 30 acres. The surface here consists of loose, porous, disintegrated, and decayed lava. In the floor of the crater there are many cracks, pits, and other openings from which hot volcanic vapors issue constantly. In several auger holes drilled in the cooler parts of the earth hot sulphurous vapor was tapped at depths of 4 to 8 feet. The ground is so hot that deposits of sulphur are not at all likely to be formed except near the surface.

The deposit includes a richer surface zone, 1 to 2 feet thick, which forms a crust, because of the sulphur deposited in it, and a subsoil zone which consists in greater part of moist, hot, porous, decomposed material, in which a small quantity of sulphur is disseminated as grains and blebs to a depth at some places of at least 16 feet.

The sulphur is very irregularly distributed, even in the crusty surface zone. Although pure sulphur occurs in masses in some of the dormant and semidormant vents, it does not extend very far down these openings. Some of these masses may include several cubic feet of apparently pure sulphur that could be mined by careful hand methods, but the aggregate space thus occupied by sulphur in the crevices and vents is relatively small, for although a few of the crevices are 10 to 12 inches wide, most of them are not more than 2 or 3 inches wide. The thickness of the sulphur-bearing crust between the crevices averages about 12 inches, although in some places it is as much as 2 feet. This crust, however, is not composed of solid sulphur, although in some places the upper 6 inches of it is chiefly sulphur. In general the lower 6 inches of a 12-inch section of the crust includes a large proportion of earth, and at many places the upper 6 inches of the deposit is also decidedly earthy.

Of the 20 or 30 acres of bare ground described probably not more than 5 acres, situated in its southern part, contains a good grade of sulphur-bearing material, and only a still smaller area contains high-grade material, even in the surface crust.

The high-grade sulphur at the open vents is about 98 to 99 per cent pure and includes about 5 per cent of the whole of the surface material. About 70 per cent of the surface material to a depth of 1 or 2 feet contains 86.3 to 89.6 per cent of sulphur, as shown by analyses of four specimens, the average content of the specimens being about 88 per cent. The average sulphur content of the surface material to a depth of 1 to 2 feet is therefore about 60 per cent. If the weight of the dried material is about 70 pounds per cubic foot (the weight indicated by the specific gravity of what was assumed to be a representative sample), the 5 acres of better ground should contain about 1,800 tons of sulphur per acre within 2 feet of the surface.

It is difficult to make even a rough estimate of the sulphur content of the remainder of the deposit, especially of the earthy part beneath the surface crust. This material is not of uniform thickness, and the quantity of sulphur that is disseminated through it is unknown. Five samples taken on the southwestern flank of the deposit from depths of about 4, 8, 10, 12, and 16 feet contain 47, 29.8, 14.7, 13.8 and 9.5 per cent of sulphur, respectively, averaging about 23 per cent. If this average holds throughout the deposit, the zone from 2 to 16 feet below the surface should contain from 716 tons of sulphur per foot per acre at a depth of 4 feet to 145 tons per foot per acre at a depth of 16 feet, or a total for the entire 14-foot zone of 4,900 tons per acre.

The sulphur-bearing area on Akun Island, on which mining claims have been located, is 1,300 to 1,500 feet above sea level and lies on the flanks of a rugged ridge about 2 miles from the shore of Lost Harbor. The sulphur-bearing area includes 15 to 20 acres, but the best part of the deposit includes only about 5 acres.

The sulphur in this deposit consists chiefly of crystalline incrustations one-sixteenth to one-eighth of an inch thick on the walls of narrow crevices and small cavities in the porous earthy surface zone. Some sulphur is also disseminated through the decomposed material, but there are practically no bodies of solid sulphur in any part of the deposit.

Most of the sulphur in this deposit occurs in the porous earthy mantle within 1 to 4 feet of the surface. The average thickness of this mantle is believed to be about 2 feet. Two samples, one taken at the surface and the other at a depth of 4 feet, contained 55.5 and 22.8 per cent of sulphur, respectively. If the average thickness of the sulphur-bearing surface mantle is 2 feet, and if its average sulphur content is 40 per cent, it should contain 1,200 tons of sulphur per acre.

Stepovak Bay is on the south shore of Alaska Peninsula in latitude 56° N., longitude 160° W. The only large sulphur deposit reported in the vicinity is about 7 miles northwest of the head of the bay at an altitude of 3,000 feet. This deposit was not visited, but a glacial moraine that extends coastward from the locality consists largely of sulphur-bearing rock, which was probably derived from it.

The sulphur-bearing rock in the morainic deposits consists of porous volcanic breccia containing compact crystalline sulphur in its interstices and in the vesicles of its constituent fragments. Some specimens of the breccia probably contain 20 per cent of sulphur in masses one-eighth inch to an inch long. The sulphur is finely disseminated through much of the breccia, of which it probably forms not more than 5 or 10 per cent. Parts of the body of the moraine may contain 10 per cent of sulphur, but larger parts of it are practically barren. The material in the moraine is probably poorer in sulphur than the bed from which it came. Some of the sulphur-bearing boulders are 30 to 40 feet thick, and thus indicate the minimum thickness of the bed or beds from which they were derived. The abundance of the sulphur-bearing material in the moraine also indicates that the original deposit was large.

PYRITES.

DOMESTIC PRODUCTION.

The domestic production of pyrites in 1918, as shown in the accompanying table, was 464,494 long tons, valued at $2,644,515, a decrease of about 18,000 long tons in quantity but an increase in value of about $50,000 as compared with the production in 1917. The consumption of pyritic ores—that is, the domestic production plus imports—amounted to about 960,000 long tons and was less even than the imports in 1917, or nearly 490,000 less tons than the consumption in that year. The decrease is largely attributable to the great falling off in imports. The following table shows the production of pyrites by the different States in 1918 so far as it may be given without disclosing confidential data regarding the production of individual companies. This production was reported by 64 mines in 15 States, or 10 mines more than in 1917.

Pyrites produced in the United States in 1918, by States.

State.	Lump.		Fines.		Total.	
	Quantity (long tons).	Value.	Quantity (long tons).	Value.	Quantity (long tons).	Value.
California	(a)	(a)	(a)	(a)	111,861	$501,541
Colorado	2,947	$6,935	15,870	$108,777	18,817	115,712
Georgia	9,334	79,526	21,981	189,271	31,315	268,797
Illinois	(a)	(a)	(a)	(a)	24,369	85,659
Missouri	(a)	(a)	(a)	(a)	7,674	69,202
New York	(a)	(a)	(a)	(a)	63,982	422,958
Ohio	9,845	40,215			9,845	40,215
Virginia	85,359	233,572	58,068	607,605	143,427	841,177
Other States b	17,640	138,549	35,564	160,705	53,204	299,254
	c 199,472	c 794,117	c 265,022	c 1,850,398	464,494	2,644,515

a Output of lump and fines are not shown separately, as there are less than three producers of one or the other.

b Includes Alabama, Kentucky, Pennsylvania, South Carolina, South Dakota, Tennessee, and Wisconsin.

c Includes quantity produced in States whose individual output may not be shown separately.

Virginia continued to be the leading State in the production of pyrites, but it produced about 27,000 tons less in 1918 than in 1917. California ranked second and produced about 4,000 tons less than in 1917. California and Virginia together furnish more than half the pyrites produced in this country. New York, the third State, and Georgia, the fourth, each showed in 1918 an increase of a few thousand tons over their respective outputs in 1917.

Of the total quantity of pyrites produced, 199,472 tons were reported to be lump and 265,022 tons were fines or concentrates. The total sulphur content of the lump ore was 74,504 tons, or an average of slightly more than 37 per cent of sulphur, and that of the fines or concentrates was 110,984 tons, or an average of about 42 per cent of sulphur. The value of the lump ore was $794,117, and of the fines or concentrates $1,850,398; the average price of the lump ore was therefore $3.98 a ton and that of the fines $7 a ton. According

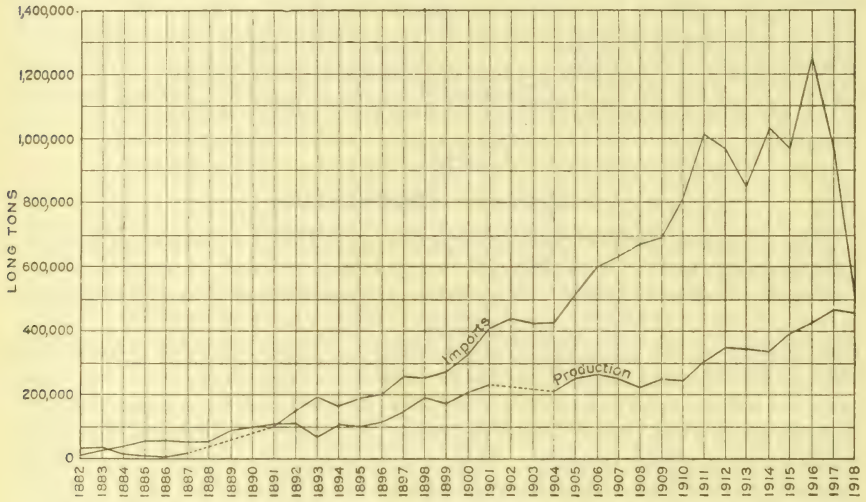

FIGURE 62.—Domestic production and imports of pyrites, 1882–1918.

to these figures the average price per unit of sulphur in the lump ore was about 10 cents and in the fines or concentrates about 16 cents.

The record of the production of pyrites from 1882 to 1918, inclusive, is graphically shown in figure 62.

Data regarding the production of pyrites in 1902 and 1903 are not available, so that the portion of the curve for these years has been projected as a straight line between the known quantities for 1901 and 1904. On the whole, there has been a rather regular increase in production, the fluctuations from year to year seldom being as much as 50,000 tons. From 1884 to 1891 the domestic production appears to have exceeded the imports; in the other years it was less.

Pyrites produced in the United States, 1909–1918.

Year.	Quantity (long tons).	Value.	Year.	Quantity (long tons).	Value.
1909	247,070	$1,028,157	1914	336,662	$1,283,346
1910	241,612	977,978	1915	394,124	1,674,933
1911	301,458	1,164,871	1916	[a] 439,132	[a] 2,038,002
1912	350,928	1,334,259	1917	[a] 482,662	[a] 2,593,035
1913	341,338	1,286,084	1918	464,494	2,644,515

[a] Revised figures.

IMPORTS.

The imports of pyrites showed a notable decrease in 1918 from those in 1917. This decrease was due in part to the difficulty of obtaining ships for the transportation of ore from Spain, but was very largely attributable to the action of the Government boards in issuing licenses for only a small part of the usual tonnage. The total imports of pyrites in 1918 amounted to 498,786 tons, less than in any other year since 1905. The annual imports from 1882 to 1918 are shown graphically in figure 62. The imports in 1888–1890, however, are not definitely known, and this part of the curve is projected as a straight line between the known quantities for 1887 and 1891.

The data for the following table were furnished by the Bureau of Foreign and Domestic Commerce:

Imports of sulphur ore as pyrites, containing more than 25 per cent of sulphur, in 1918, by countries and districts of entry.

Country exporting.	1918		Districts of entry.	1918	
	Quantity (long tons).	Value.		Quantity (long tons).	Value.
Canada	221,612	$939,143	Buffalo	45,764	$214,807
			Chicago	72,135	334,227
			Duluth-Superior	12	250
			Michigan	451	1,889
			Ohio	74,966	318,158
			St. Lawrence	30	300
			Vermont	28,084	67,812
			New York	170	1,700
England	1,959	6,638	New York	1,959	6,638
France	4,566	67,150	Philadelphia	4,566	67,150
Spain	270,649	1,754,517	Florida	17,263	75,521
			Georgia	26,648	108,507
			Maryland	36,853	205,615
			Massachusetts	8,693	28,576
			New Orleans	3,212	11,047
			New York	62,756	412,253
			Philadelphia	78,543	748,854
			South Carolina	26,269	100,426
			Virginia	10,412	63,718
	498,786	2,767,448		498,786	2,767,448

A comparison of this total with the similar one for 1917 shows that imports from Canada increased nearly 7,500 tons in 1918 and that the imports from Spain decreased about 477,000 tons. The quantity of pyrites imported from Canada was much less than had been predicted and the falling off was doubtless due to the abundance of domestic crude sulphur available in the United States. The pyrites reported to have been imported from France and England is believed to have been produced in and shipped from some other country and then reshipped and thus credited to these countries that as a rule do not produce pyrites for shipment.

The value of the imported pyritic ore as stated by the Bureau of Foreign and Domestic Commerce was $2,767,448, an average price of $5.55 a ton. The average price of the ore imported from Canada was less than $4.25 a ton. The average price of the Spanish ore was nearly $6.50 a ton. Some of the difference in price is warranted by the generally high sulphur content of the Spanish ore, but some of the difference is caused by the unwillingness of the users of pyrites to modify their former practice and accept any substitute if Spanish ore is obtainable even at an extra cost.

The cessation of hostilities has had a considerable effect on increasing the imports of Spanish ore and this effect will doubtless be even greater in the future unless tariff or other governmental restric-

tions are placed on the free movement of this commodity. Licenses are no longer required, and the shortage of ships and the availability of crude sulphur are the main obstructions to a resumption of the former rate of importation. Recent quotations in the technical press (April and May, 1919) show that Spanish pyrites are quoted at about 20 cents a unit c. i. f. New York or any of the Atlantic ports.

CHARACTER OF DOMESTIC DEPOSITS.

The iron sulphides are very common minerals, being found in all parts of the country and in almost all kinds of rocks. In order to be of value, however, they must occur in deposits capable of yielding a considerable quantity relatively free from worthless material and must be so situated that they can be cheaply mined and transported to market.

In the United States, there are four main areas in which pyrites is so abundant that deposits of pyrites may be sought in them with some promise of success. These areas, enumerated from east to west, are the Appalachian Mountain region, where pyrites occurs in lenses associated with schists and crystalline rocks; the interior States, where it is mainly associated with coal beds; the Rocky Mountain States, where, in places, it occurs in numerous veins and lenses often mixed with sulphides of copper, lead, and zinc; and the Coast Ranges, where it usually occurs in lenses more or less intimately associated with igneous rocks.

More than three-quarters of the domestic and imported pyrites consumed in the United States is used in the region east of Mississippi River. As a consequence, although there are enormous deposits of pyrites in the western part of the country, most of the deposits in the Rocky Mountain States and farther west can not be profitably utilized under present conditions.

In most coal mines pyrites is separated from the coal when the coal is prepared for market, and at a few mines this pyrites is saved and sold. In general, it is discarded as waste, several hundred thousand tons being thus discarded every year. Usually, however, its recovery would cost more than it is worth, for if pyrites is separated from the coal underground it requires special sorting and when it is hoisted to the surface it interrupts and delays the hoisting of the coal. In some districts attempts to recover the pyrites contained in the waste from the coal washeries have been made, but usually the quantity of this material from any one mine is not sufficiently great to pay for the installation of the necessary equipment. Furthermore, the manufacturers of sulphuric acid—the main users of pyrites—have not been disposed to purchase the pyrites recovered from coal. Some of this reluctance is due to the fact that pyrites containing carbon (coal) is likely to take fire easily, makes a dark-colored acid, requires the use of more niter, and decreases the capacity of the acid plant. Extensive experiments under the direction of E. A. Holbrook[1] have shown that by the use of appropriate ore-dressing treatment the pyrites can be cleaned so thoroughly of adhering coal as to remove many of these objections. The unwillingness to use pyrites from coal, or "coal brasses," is clearly reflected in the low price paid for pyrites from this source. According to the table on page 371 the

[1] Holbrook, E. A., The utilization of pyrites occurring in Illinois bituminous coal: Illinois Univ. Eng. Exper. Sta., Aug. 20, 1917.

value per ton of pyrites produced in Illinois was $3.52 and of that produced in Ohio, $4.08. All of this pyrites was obtained from coal deposits. These prices may be contrasted with the prices paid for pyrites that was not derived from coal deposits, which were $5.86 a ton in Virginia, $6.61 a ton in New York, and $8.58 a ton in Georgia.

The chapter on sulphur, pyrites, and sulphuric acid in Mineral Resources for 1917 contained a fairly complete statement regarding the deposits of pyrites that were being mined or appeared likely to be developed. In these descriptions the main facts regarding the location of the different deposits, the size and extent of the ore bodies and their geology, and the general tenor of the ore were given as fully as the data available permitted. That report should therefore be consulted by those who desire further information regarding the type of deposits of pyrites in any part of the country. Not only does that report furnish a summary statement regarding the various deposits but it also gives references to published reports on special areas or deposits from which still more detailed information may be obtained.

Since the chapter of Mineral Resources noted above was published, a bulletin on the deposits of pyrites in Georgia has been issued by the Geological Survey of that State.[1] That bulletin gives much detailed information regarding the deposits of pyrites in Georgia and is illustrated by diagrams, maps, and pictures which show graphically many of the significant facts regarding the deposits. According to that report, the deposits of pyrites show a great variation in character of ore and associated rocks. There are four main types—metamorphosed pyrite veins, generally associated with the so-called Roan gneiss; limestone replacement; pyrrhotite veins; and disseminated deposits in basic rocks. Deposits of the first two types are the only ones that are known to be of commercial value.

USE IN SULPHURIC ACID INDUSTRY.

The use of pyrites and sulphur is so closely related to the production of sulphuric acid and that acid enters so largely into all industries that for the last seven years it has been the practice of the Geological Survey to collect statistics of the production of sulphuric acid. So many of the new war organizations, however, entered this field, and so many data were gathered, and the producers were engaged in filling in so many questionnaires that the Geological Survey abandoned its collection of statistics relating to this industry. It is felt, however, that information regarding the sulphuric acid industry is so important in its relation to the sulphur and pyrites industries that the following quotation of the published statement on the subject by A. E. Wells,[2] of the Bureau of Mines, who also served as a member of the War Industries Board, is given:

> On January 1 of this year [1918] the total manufacturing capacity of the country for acid was 427,000 tons per month (basis 100 per cent H_2SO_4), or 8,200,000 tons per year (basis 50° B.), of which 29 per cent was at contact acid plants.
>
> On November 1 of this year the total manufacturing capacity of the country was 500,000 tons per month (basis 100 per cent H_2SO_4), or 9,600,000 tons per

[1] Shearer, H. K., and Hull, J. P. D., Pyrite deposits of Georgia: Georgia Geol. Survey Bull. 33, 229 pp., 1918.

[2] Wells, A. E., Present sulphuric-acid capacity and estimates of requirements for 1919: Committee on Fertilizers of Chemical Alliance Weekly Bull. 82, Dec. 21, 1918.

year (basis 50° B.). Of this total capacity 40 per cent was at contact acid plants.

This capacity was divided among (1) Government, (2) explosives companies, (3) all others, including commercial manufacturers, by-product manufacturers, etc., as follows:

	Expressed as tons per month (100 per cent H_2SO_4).	Expressed as tons per year (50° B.).
(1) At Government plants	54,000	1,040,000
(2) At plants of explosive manufacturers	58,000	1,120,000
(3) All others	388,000	7,440,000
	500,000	9,600,000

Inasmuch as the acid market conditions in the intermountain and Pacific coast districts are quite distinct from those in the East, and as there has been brought about very little, if any, disturbance in those districts, except for possibly some slight disturbance in the San Francisco district, it is not necessary to include the figures for those districts in the discussions regarding eastern conditions.

The total capacity east of the Mississippi River, and also including the plant at Argentine, Kans., and the plants in Louisiana and Arkansas, is as follows:

	Tons per month (as 100 per cent H_2SO_4).
(1) At Government plants	54,000
(2) At plants of explosives companies	50,000
(3) All others	350,000
	454,000

If we assume that the Government plants and the contact plants, which were built by the explosives companies primarily to supply acid for munitions explosives, are not operated in 1919 or, if operated at all, the production will be utilized only for munitions and thus will not be placed on the market, there remains a total capacity to be considered in the eastern part of the United States amounting to 365,000 tons per month (basis 100 per cent H_2SO_4), or 7,000,000 tons per year (basis 50° B.).

During the first nine months of 1918 the actual rate of production was only about 90 per cent of the rated maximum capacity, although many plants were operating much above the rated capacities. Therefore, it is fair to conclude that the probable maximum output from these plants during the year 1919 can not be greater than 90 per cent of the rated capacity, or, in other words, the maximum output could be only about 328,000 tons per month (basis 100 per cent H_2SO_4), or 6,300,000 tons per year (basis 50° B.).

During the months of June, July, and August, 1918, the following industries in the eastern part of the United States consumed approximately the following tonnage of acid:

	Tons per month (basis 100 per cent H_2SO_4).
1. Domestic explosives	7,500
2. Fertilizers	109,400
3. Chemicals and drugs, including nitric acid, hydrochloric acid, ammonium sulphate	37,600
4. Oil refining	28,700
5. Steel pickling and galvanizing	36,200
6. Fabrics, textiles, tanning, rubber, paper, bleaching	5,100
7. Paints, lithopone, dyes, glue, glycerine, alcohol	6,200
8. Storage batteries, metallurgical work	4,700
9. Miscellaneous and unknown	4,600
	[1] 240,000

[1] Or 4,600,000 tons per year (basis 50° B.).

It is believed that the consumption of acid in the various industries during the period as given above offers a better basis for estimating the future consumption during 1919 than any reference to the figures of 1914. However, it may be stated by way of comparison that in the eastern half of the United States there were consumed in 1914 about 3,500,000 tons of acid (basis 50° B.), according to the figures compiled by the United States Geological Survey. From these figures, it is evident that between the years 1914 and 1918 there was an increase in the requirements of acid for industries, other than munitions explosives, amounting to about 1,000,000 (basis 50° B.). The consumption of acid for fertilizers will undoubtedly be greater in 1919 than in 1918, and will probably average at least 130,000 tons per month (basis 100 per cent H_2SO_4), or 2,500,000 tons per year (basis 50° B.). Thus, with general business conditions favorable, the average monthly consumption of acid in the above industries in the eastern part of the country during the year 1919 should not be less than 260,000 tons per month (basis 100 per cent H_2SO_4), or 5,000,000 tons per year (basis 50° B.). This would require operating all the plants at about 71 per cent of the rated maximum capacity, if the business was distributed over the district proportionately to the manufacturing capacity in the various districts. As a matter of fact, the southern fertilizer plants will probably operate to full capacity, while plants in Boston, New York, Philadelphia, and Baltimore districts may have to average less than 70 per cent of the rated capacity.

The production and consumption of acid in the western half of the United States will probably be about 500,000 tons per year (basis 50° B.), so that the total production for the whole country will be about 5,500,000 tons in 1919.

A discussion primarily of the prices of mineral acids, prepared by H. L. Lewenberg,[1] gives much information not only concerning the sulphuric acid industry but incidentally concerning the supplies of raw materials from which the acid is made. Among other significant statements contained in this report the following table showing the quantity of 50° Baumé sulphuric acid produced from the various sulphur materials for 1918 as estimated in the summer of 1918 is of particular interest because of its bearing on the sulphur and pyrites industry:

	Tons of 50° Baumé acid produced.
Sulphur	4,270,000
Domestic pyrites	1,150,000
Zinc ore fumes	900,000
Copper ore fumes	800,000
Spanish pyrites	600,000
Canadian pyrites	480,000
	8,200,000

The report by Mr. Lewenberg contains a tabulated statement and a chart showing graphically the relative prices of sulphur and pyrites, by months, from January, 1913, to December, 1914, the average quoted price for July, 1913, to June, 1914, being taken as 100 per cent.

SILICA (QUARTZ).

By Frank J. Katz.

INTRODUCTION.

Silica (SiO_2), which is commonly known as quartz or flint, occurs abundantly throughout the United States in deposits of commercial importance in many different forms—as vein quartz, as a constituent of pegmatites, as sand, sandstone, quartzite, novaculite, flint, or chert, and as tripoli and diatomaceous (infusorial) earth. In some of its natural forms, such as rose, smoky, and amethystine quartz, it has value as gem material. This chapter deals with silica of all kinds except gem quartz, silica used for making glass, and silica used in the form of sand, gravel, and crushed material for building, for concrete and mortar, for foundry and furnace work, and for cutting and grinding stone. Such material as is not here included is either gem material or sand, is commercially so designated, and is therefore considered in other chapters of Mineral Resources. Tripoli and diatomaceous earth are to a large extent consumed as abrasives and are considered in the chapter on abrasive materials.

USES.

Silica (quartz) as considered in this chapter is used for many purposes, principally in the manufacture of pottery, paints, and scouring soaps, as a wood filler, as a polisher, as foundry mold wash in metallurgical and chemical processes, and in small quantities for cosmetics, dentifrices, and numerous other minor uses. In the pottery industry, where it is generally called flint, silica is used in the body of the ware to diminish shrinkage, and is also used in glazes. Silica for use in pottery should contain less than 0.5 per cent of iron-bearing minerals. Manufacturers of paint use considerable quantities of very finely ground silica, which forms as much as one-third of the total pigment in some paints. For certain purposes finely ground crystalline material is superior in paints to other materials because of the angularity of the grains, which makes them adhere more firmly to the article painted and after wear affords a good surface for repainting. The same angularity makes artificially comminuted crystalline quartz superior to natural sand for use in wood fillers. For soaps and polishing powders ground material is preferred to natural sand on account of its whiteness and angularity. For all these purposes large quantities of pure quartz sand and sandstone are finely ground and yield a product fully equal to that obtained by grinding massive crystalline quartz.

Quartz crushed and graded to various sizes is used in making sandpaper and sand belts, as a scouring agent, for "frosting" glass with sand-blast apparatus, and for other purposes. Blocks of massive quartz and quartzite are used in the chemical industry as a filler for acid towers and as a flux in copper smelting. Ground quartz is

also used in filters and in tooth powders and by dentists as a detergent.

Sand and crystalline quartz have been used in making silicon and alloys of silicon with iron, copper, and other metals in the electric furnace. Quartz may be fused in the electric furnace to make chemical apparatus, such as tubes, crucibles, and dishes.

The material known commercially in the United States as tripoli, which is the siliceous residue of decomposed limestones, also yields an excellent grade of pulverized silica, which is used for the same purpose as silica powder obtained from massive crystalline quartz and from sands and sandstones. Diatomaceous (infusorial) earth is also used to make polishing powder that is employed for similar uses to those for which quartz, sand, and tripoli powders are employed, but diatomaceous earth has somewhat different properties and most of it finds different application, as insulating and filter material.

PRODUCTION.

The reports to the United States Geological Survey on the production in 1918 of silica for various uses considered in this chapter are summarized in the following table. The combined output of these materials decreased 73 per cent in quantity and 41 per cent in value in 1918, as compared with 1917.

Silica sold for pottery, paints, fillers, polishers, abrasives, and other uses in 1916, 1917, and 1918.

Material.	1916		1917		1918	
	Quantity (short tons).	Value.	Quantity (short tons).	Value.	Quantity (short tons).	Value.
Quartz (vein quartz, pegmatite, and quartzite)	88,514	$242,786	142,673	$318,069	71,740	$259,330
Sand and sandstone [a]	110,603	489,863	532,454	1,195,142	98,956	620,584
Tripoli (ground and otherwise prepared)	43,257	215,216	26,069	338,188	19,982	199,854
Diatomaceous earth [b]	2,721	26,337	3,033	31,368	2,965	24,947
	245,095	974,202	704,229	1,882,767	193,643	1,104,715

[a] Includes only finely ground material. Figures probably incomplete.
[b] Excludes California product used for filters and as insulating and fireproofing material.

These figures clearly reflect the influence of war conditions on the silica industry. In only those uses, particularly for foundry mold wash and for grinding and polishing, of which the war required increased output, was there increased demand for silica. The consumption in pottery, paints, wood filler, and finishing abrasives for woodworking was largely curtailed either directly as nonessential or indirectly by demands on manufacturing plants for other lines of production.

SILICA INDUSTRY IN 1918, BY STATES.

Alabama.—Only a very small silica output in 1918 was reported from Trussville, Jefferson County, Ala. The production of silica refractories, cleansing, and abrasive materials in Calhoun and Jefferson counties has ceased.

Arizona.—A small output of quartz for copper smelting was reported from Cochise County, Ariz.

California.—California in 1918 produced 3,544 short tons of quartz, valued at $4,489. The output was made by the Eldorado Lime & Mineral Co., of San Francisco, from quartz boulders collected at Ione, Amador County, and was used as flux and in the manufacture of silica brick; by Alva Joyner at Exeter, Tulare County, and used for porcelain; by Charles Biedleman at Blaine Ranch, Tulare County, and used for porcelain; by J. LaKamp from quartz boulders at Dutch Flat, Placer County, and used chiefly for foundry molds; by Thompson & LaBorde at Lakeview, Riverside County, and used for porcelain and glass. The following California firms have been reported as silica grinders: West Coast Porcelain Manufacturing Co., Millbrae; Pacific Porcelain Ware Co. and Pacific Sanitary Co., Richmond; Stockton Fire & Enamel Brick Co., Stockton; Judson Manufacturing Co., Emeryville.

Colorado.—The production of silica in Colorado in 1918 was reported by the Standard Fire Brick Co. from quartzite quarried at Carson City and Parkdale, Pueblo County, and by M. D. Funk, at Wray, where the output was used for manufacturing cleansing compounds. The production of quartz in Colorado for metallurgical flux has not been recorded.

Connecticut.—The output of quartz in Connecticut in 1918 came from Litchfield, Litchfield County; it was obtained by the Lithowhite Silex Co., and was ground at Still River, Conn., for use in soap, pottery, paint, and other manufactures. This company's Still River mill also ground quartz obtained at Cheshire, Mass.

The quarries on Lantern Hill, North Stonington, New London County, which were formerly a source of considerable silica, did not produce in 1918, but plans for a new grinding plant and future production were under consideration.

Connecticut produced also a little diatomaceous earth.

Illinois.—The sandstone quarries of La Salle and Ogle counties, Ill., produce large quantities of silica, most of which is reported in the sand and gravel chapter of Mineral Resources. The National Silica Co., at Oregon, Ogle County, and the Wedron Silica Co., at Wedron, La Salle County, ground in 1918 many thousands of tons which are included in the above table and which were used for pottery, paints, and foundry mold wash. Illinois sand and sandstone are also ground by silica mills in Wisconsin, Ohio, and Pennsylvania. The State also contributed heavily to the silica supplies of the country from the tripoli deposits in Alexander and Union counties. This output is reported in the abrasives chapter of Mineral Resources.

Maine.—Quartz was produced in Maine in 1918 from pegmatites, which were also worked for feldspar, by the Trenton Flint & Spar Co., at Cathance, Sagadahoc County, and by the Maine Feldspar Co., near Danville, Androscoggin County. The product was used for pottery and for the manufacture of ferrosilicon.

Maryland.—The quartz output in Maryland is derived from quartz veins and pegmatites. In 1918 the marketed product was 6,826 short tons of crude quartz, valued at $22,969, and 2,189 short tons of ground quartz, valued at $24,827. The active producers were S. P. Dunkel & Son, Baltimore, who worked a quartz vein near Florence in Howard County; the Guilford & Waltersville Granite

Co., of Baltimore, which works pegmatite near Granite, Baltimore County; the Indian Rock Flint Co., which works quartz veins near and a mill at Conowingo, Harford County; the Maryland Quartz Co., of Baltimore, which grinds in a mill at Glen Morris, Baltimore County, vein quartz collected in that vicinity; Thomas & Son, of Westminster, who obtain quartz from veins and pegmatites in Carroll County near Marriottsville; H. Clay Whiteford & Co., of Flintville, who work a quartz vein and a mill near Flintville. The Maryland product is used largely for pottery, but also for wood filler, for abrasive soaps, for packing acid towers, and otherwise in the manufacture of chemicals and for filters.

Massachusetts.—The very large production of silica "sand" from the quartzite near Cheshire, Mass., is covered in the chapter on sand and gravel. A part of it, however, is used for abrasives, paints, fillers, and for other uses here considered. This part was produced by the Enos Adams Co., of Bennington, Vt., and the Cheshire White Quartz Sand Co. and the Lithowhite Silex Co., of Litchfield, Conn. The last-named company ground most of its Massachusetts product at Still River, Conn.

Michigan.—In Michigan there was one silica producer in 1918, as in previous years—the Michigan Quartz Silica Co., of Milwaukee, Wis. Vein quartz and quartzite are obtained in Ishpeming, Mich., and are ground at the company's plant in North Milwaukee. The product is used chiefly as a wood filler, also in paint, and to a small extent for other purposes.

Nevada.—A milling plant was reported in process of construction near Beatty, Nye County, Nev., where a pure quartzite is to be quarried and prepared for use in making glass, soap, fillers, paint, and enamel ware. The plant began operations January 3, 1919.

New Jersey.—A large output of sand from Camden County, N. J., was ground by the Pennsylvania Pulverizing Co., Williamstown Junction, for use in pottery, scouring soaps, and mold wash.

New York.—Quartz quarries at Bedford and Newcastle, Westchester County, N. Y., were operated by the Bedford Mining Co., Bedford, N. Y., in 1918. Most of the output was ground in Connecticut and used in making pottery, paint, wood filler, and soap.

North Carolina.—Quartz was quarried in 1918 by the Oliver Quartz Co., Charlotte, N. C., near Mount Holly in Gaston County, Wadeville in Montgomery County, and Norwood in Stanly County, and by Claud Hafer at Troy in Montgomery County. The output was used largely for packing acid towers; part was ground and otherwise prepared for use in the manufacture of acid-proof cements. A quantity of quartz for copper smelting was obtained in the vicinity of Murphy, Cherokee County.

Ohio.—No production of quartz was reported from Ohio in 1918, but large quantities were ground in the State and sold to local potteries and other manufactories.

Pennsylvania.—In 1918 quartz was marketed by two producers in Pennsylvania. The Columbia Flint Co. worked quarries in quartz veins near Bendersville and operated a mill at Aspers, Adams County, and H. T. A. Rhodewalt worked a quartz vein near Cornog, Chester County. In addition to this output of vein quartz the Pennsylvania Pulverizing Co., Lewistown, Pa., made a large output of ground silica derived from sandstones quarried and ground at Granville

and Dawson Mills, Mifflin County. The combined silica production of Pennsylvania in 1918 was 39,554 short tons, valued at $257,463, and was used for pottery, enamel ware, mold wash, sandpaper, and abrasive soaps.

Tennessee.—In 1918 Tennessee produced a large quantity of quartz, but the material was of comparatively low grade and of small value. It was used by the Tennessee Copper Co. and the Ducktown Sulphur, Copper & Iron Co. as flux in copper smelting.

Virginia.—Material (said to be vein quartz) obtained at Mendota, Washington County, Va., in 1918 was marketed for use in polishing and cleansing compounds in Bristol, Tenn.

West Virginia.—Two producers in West Virginia—the National Silica Works, at Berkeley Springs, and the Pennsylvania Pulverizing Co., at Hancock station, Morgan County—ground sand and sandstone for use in the manufacture of pottery, scouring soaps, paints, and for mold wash.

Wisconsin.—The Wausaw Quartz Co., operating at Flieth, Marathon County, Wis., produced quartz in 1918. The product is derived from a very pure quartzite and is used for filter beds, for roofing, for concrete work, for chicken grits, and for sandpaper. The Michigan Quartz Silica Co. operated a silica mill at North Milwaukee, grinding material obtained in Michigan and elsewhere.

FLINT OR CHERT.

PRODUCTION.

So far as can be learned no true flint or chert has been produced for consumption as crushed or ground silica in grinding mills in the United States. The manufacture of flint, chert, and quartzite blocks for tube mill lining is reported in the chapter on abrasive materials.

IMPORTS.

The Department of Commerce records imports of "flint, flints, and flint stones, unground," from several countries. These imports are partly flint pebbles for use in grinding mills and partly material for such uses as are listed in this report. The accurate separation or classification of these materials is impossible. The imports of flint "for consumption" into the United States in 1918 were valued at $135,636, compared with $197,156 in 1917, $313,120 in 1916, $274,904 in 1915, $432,694 in 1914, and $324,662 in 1913. A detailed table of imports of flint pebbles of various kinds, by countries, and a discussion of domestic substitutes for foreign flint pebbles are given in the chapter on abrasives in Mineral Resources for 1917.

QUARTZ.

PRODUCTION.

Quartz from quartz veins, pegmatite, and quartzite, amounting to 71,740 short tons and valued at $259,330, was sold in 1918. This was a decrease in quantity of 50 per cent and in value of 18 per cent, as compared with 1917. There was marked decrease in sales of both crude or crushed and ground quartz, and the combined sales of both were less in quantity than has been reported in any year since 1910.

This falling off was due not only to curtailment of the consuming industries by the war, but also to the growing tendency to replace quartz from these sources by sand and sandstone. The quartz (or silica) here considered was produced in Alabama, Arizona, California, Colorado, Connecticut, Maine, Maryland, Massachusetts, Michigan, New York, North Carolina, Pennsylvania, Tennessee, and Wisconsin.

Prices of crude and crushed quartz ranged from $1 to $7.50 a short ton, and, exclusive of large quantities nominally valued at $1 and used in copper smelting, averaged about $3.47 a ton, as compared with $3.25 in 1917, $2.37 in 1916, and $3.30 in 1915. Prices for finely ground, pure quartz commonly ranged from $9 to $18.50 a ton, with exceptional lots selling as high as $40. The average price computed on total sales was $12.80, as compared with $12.25 in 1917, $9.09 in 1916, and $10.56 in 1915.

Quartz sold in the United States, 1910–1918.

Year.	Crude.		Ground.		Total.

POTASH.

By W. B. Hicks.

INTRODUCTION.

Only potash materials derived from original sources such as alunite, brine, and kelp have heretofore been included under domestic production in the annual reports on potash. Such materials vary greatly in composition and content of potash, and are used as fertilizers or as raw materials in the production of potassium compounds. They include among other materials more or less refined potassium sulphate derived largely from alunite, potassium chloride, and crude mixed salts derived largely from brines and kelp, and crude potassium carbonate derived from wood ashes. Their value depends essentially on the percentage of actual potash (K_2O) present in soluble form in the materials as marketed.

Refined potassium salts, which constitute a large part of the subject matter of the present report, may be obtained from original sources—for example, potassium sulphate from alunite—but most of them are manufactured from other potassium salts used as raw materials either imported or of domestic origin. They are used largely in chemical industries. Their inherent value often depends on the properties of the acid radicles with which the potassium is combined rather than on the properties of potassium. For example, it is primarily the oxidizing power of the nitrate and chlorate radicles and not the properties of the potassium that determines the use of potassium nitrate and potassium chlorate in explosives. Therefore, it is not surprising that the more economical sodium salts are gradually replacing potassium salts in chemical industries. At the same time slight differences in properties give certain potassium salts a superiority over the corresponding sodium salts and make them preferred in many applications and absolutely necessary in others. For instance, potassium chlorate, permanganate, and bichromate crystallize well and are easily purified, but the reverse is true of the corresponding sodium salts. Furthermore, the hygroscopic nature of sodium nitrate and of sodium chlorate preclude their use in explosives and matches, except under very special conditions.

The statistical data relating to the domestic production of refined potassium salts in 1918 have been compiled from reports submitted by producers and elicited through correspondence. Inquiries were sent to all firms thought to be interested in the production of potassium salts; practically all of them responded and most of them coop-

erated generously in giving the information requested. Although some producers may not have been reached, the compilation is believed to be practically complete.

DOMESTIC PRODUCTION.

POTASH MATERIALS DERIVED FROM ORIGINAL SOURCES.

The potash-bearing materials reported to the United States Geological Survey as produced in the United States in 1918 amounted to 207,686 short tons, having an approximate average content of potash (K_2O) of 26.4 per cent. This was equivalent to a total content of 54,803 short tons of potash (K_2O). Actual sales amounted to 38,580 short tons, valued at $15,839,618, or $4.11 per unit of potash. The production in 1917 was 126,961 short tons of potash-bearing materials, having an average content of 25.6 per cent of K_2O, or a total content of potash of 32,573 short tons, valued at $13,980,577, or $4.29 per unit of potash. The production in 1918 was, therefore, nearly 70 per cent more than in 1917, and it represented about 22 per cent of the normal consumption in the country, which is estimated to be about 250,000 short tons of potash annually. The following table shows the increase in the domestic production of potash during the last few years and gives some idea of the growth of the industry:

Potash produced and sold in the United States, 1915–1918.

Year.	Number of producers.		Production.		Sales. [a]		
	Total.	Exclusive of producers of wood-ash potash.	Crude potash (short tons).	Available content of potash (K_2O) (short tons).	Crude potash (short tons).	Available content of potash (K_2O) (short tons).	Value f. o. b. plant.
1915	[b] 5	5	4,374	1,090	4,374	1,090	$342,000
1916	70	25	35,739	9,720	35,739	9,720	4,242,730
1917	95	46	126,961	32,573	126,961	32,573	13,980,577
1918	128	77	207,686	54,803	140,343	38,580	15,839,618

[a] Production and sales were practically the same from 1915 to 1917, and no distinction was made between them.

[b] Although no production was reported from wood ashes it is probable that an appreciable quantity of potash was produced from that source in 1915.

In 1918 the production came from 10 distinct classes of raw materials. Natural brines furnished about 73 per cent of the output, the Nebraska lakes alone contributing about 53 per cent and Searles Lake, Calif., the second largest quantity from a single source. Kelp yielded about 9 per cent of the total production, followed by smaller contributions from molasses, alunite, cement, etc. The figures of production for 1918, classified according to sources, are shown in the following table.

Potash produced and sold in the United States in 1918, classified according to sources.

Source.	Number of producers.	Production.			Sales.		
		Crude potash (short tons).	Available content of potash (K_2O).		Crude potash (short tons).	Available content of potash (short tons).	Value f. o. b. plant.
			Quantity (short tons).	Percentage of total.

	128	207,686	54,803	100	140,343	38,580	15,839,618

Potash materials marketed in 1918 varied greatly in composition and in content of potash. Crude mixed salts, containing 20 to 28 per cent of potash (K_2O) and composed largely of carbonates and sulphates of sodium and potassium, constituted about 58 per cent of the output; muriate, containing 60 to 96 per cent of potassium chloride, equivalent to 38 to 62 per cent of potash, about 24 per cent; sulphate, containing 35 to 51 per cent of potash, 6 per cent; and low-grade chloride, crude carbonate, caustic, potash char and ash, cement and blast-furnace dust, and miscellaneous the remainder. Most of the muriate[1] was of low grade and much of it contained borax, while the larger portion of the sulphate was of high grade. Crude carbonate and caustic was largely the product made from wood ashes. As marketed, much of the carbonate contained about 70 per cent of potassium carbonate mixed with about 30 per cent of potassium sulphate and other impurities. Considerable quantities were converted into caustic, which contained between 80 and 90 per cent of potassium hydroxide, equivalent to about 70 to 75 per cent of potash (K_2O). Potash char and ash came from kelp, molasses distillery waste, and Steffens waste water, and contained 24 to 44 per cent of potash in the form of mixed salts along with considerable quantities of insoluble matter. The products classified as miscellaneous include ground kelp, residues from molasses distillery waste, concentrated Steffens waste water from beet-sugar refineries, alum, calcined alunite, and vegetable ash.

[1] See also regarding muriate, p. 427; sulphate, p. 436; crude carbonate, 424; and caustic, p. 430.

Potash produced in the United States in 1918, classified according to product marketed.

Potash material.	Crude potash (short tons).	Available content of potash (K_2O).		
		Percentage.	Quantity (short tons).	Percentage of total.
Crude mixed salts	124,467	20–38	31,793	58
Muriate	31,486	38–62	13,184	24
Sulphate	6,897	35–51	3,294	6
Low-grade chloride	6,589	10–25	901	2
Crude carbonate	914	40–70	533	1
Caustic [a]	262	40–80	172	
Potash char and ash	6,875	24–44	2,203	4
Dust from cement and blast furnaces	13,557	2–9	938	2
Miscellaneous [b]	16,639	4–20	1,785	3
	207,686	2–70	54,803	100

[a] The larger portion of the caustic contained about 75 per cent of K_2O. About one-fourth of it was sold in solution which contained from 40 to 45 per cent of K_2O. See page 430.

[b] Includes ground kelp, low-grade materials from molasses distilleries and beet-sugar refineries, alum, calcined alunite, and plant ashes.

Approximately 53 per cent of the total production came from Nebraska, 34 per cent from California, 7 per cent from Utah, and the other 6 per cent from 18 other States and Porto Rico. About 95 per cent came from Western States and was handicapped by freight rates of about 50 cents per unit of potash (K_2O) to the eastern markets. The production classified according to States is shown in the following table:

Potash produced in the United States in 1918, classified according to States.

State.	Number of plants.	Crude potash (short tons).	Available content of potash (K_2O).	
			Quantity (short tons).	Percentage of total.

STOCKS.

Nearly 70,000 short tons of crude potash containing more than 16,000 tons of potash (K_2O) was reported as produced during 1918 in excess of sales and held by producers at the end of the year, as appears from the following table:

Potash held by producers in the United States at the end of 1918.

Sources.	Stocks.	
	Crude potash (short tons).	Available content of potash (K_2O) (short tons).

REFINED POTASSIUM SALTS.

The domestic production of refined potassium salts in 1918, exclusive of chlorides and sulphates, as reported to the United States Geological Survey, amounted to 53,661,676 pounds, and the sales amounted to 43,833,503 pounds, valued at $16,032,880. Forty-seven firms reported production, and it is probable that a few firms failed to make returns. The figures are classified in the following table with as much detail as is consistent with the confidential nature of the individual reports submitted.

Refined potassium salts produced and sold in the United States in 1918.[a]

Potassium salt.	Number of firms.	Production (pounds).	Sales.	
			Quantity (pounds).	Value.
Acetate	5	93,307	90,229	$59,314
Aluminum sulphate (alum)[b]	3	10,922,955	9,699,645	251,181
Bromate, iodate, and perchlorate	3	513,100	510,699	243,198
Bromide	3	666,119	616,232	551,079
Carbonate and bicarbonate[c]	4	229,287	201,574	104,432
Chlorate	3	9,753,424	9,753,424	2,837,892
Chromate and bichromate	4	681,346	1,003,598	407,793
Citrate	6	99,193	96,273	141,517
Ferrocyanide	3	457,267	306,535	204,190
Hydroxide (caustic)	14	1,984,847	1,594,580	856,148

Nitrate	4	16,250,433	8,176,382	2,206,788
Permanganate	9	562,416	530,837	922,746
Tartrates[d]	5	10,869,874	10,717,674	5,596,732
All others[e]	3	56,430	54,520	62,214
	.....	53,661,676	43,833,503	16,032,880

[a] For the production of potassium chloride, potassium sulphate, and other products derived from original sources see page 388.

[b] Includes both the hydrous (potash alum) and the anhydrous (burnt alum) salt.

[c] In addition, 1,827,000 pounds of crude carbonate from wood ashes was produced, and 1,753,000 pounds, valued at $331,000, was sold. See page 424.

[d] Includes neutralacid (cream of tartar), sodium (Rochelle salt), and antimony, (tartar emetic) tartrates.

[e] Includes bisulphate, bisulphite, ferricyanide, oxalate, phosphate, sulphide, and sulphite.

The following table summarizes the available data on the production of refined potassium salts in 1914. Figures for 1915, 1916, and 1917 have not been compiled.

Refined potassium salts produced in the United States in 1914.[a]

Salt.	Number of producers.	Quantity (pounds).	Value.
Potassium aluminum sulphate:			
Potash alum	5	12,765,000	$219,968
Burnt alum	4	22,629,000	364,656
Potassium carbonate[b]	.....	.....	49,651

All others[c]	[d]42	.....	2,801,225
	.....	80,724,804	8,255,601

[a] Chemical and allied industries: U. S. Dept. of Commerce Bur. Census, census of manufactures, 1914.
[b] Includes crude, unrefined, and refined carbonate.
[c] Includes potassium acetate, bicarbonate, chlorate, citrate, hydroxide, iodate, and silicate.
[d] Includes 17 wood-ash potash producers and producers of nitrate, carbonate, and items listed under "All others."

IMPORTS.

In contrast to the large quantity and low cost of German potash used in the United States before the war, the imports in 1918 amounted to only 7,957 short tons of potash (K_2O), valued at $8,907,836, or $1.12 per unit of potash (20 pounds of K_2O), as rated in import returns. Imports from 1913 to 1918 are classified according to materials imported in the following table:

Potash materials imported and entered for consumption in the United States, 1913–1918.[a]

Material.	Approximate potash (K_2O) content (per cent).	1913				1914				1915			
		Quantity (short tons).	Available content of potash (K_2O).		Value.	Quantity. (short tons).	Available content of potash (K_2O).		Value.	Quantity. (short tons).	Available content of potash (K_2O).		Value.

[a] The figures in this table were compiled from the records of the Bureau of Foreign and Domestic Commerce, United States Department of Commerce, by recalculation to short tons and to actual potash (K_2O) and by giving the totals for calendar years instead of fiscal years. The tons are calculated to the nearest even unit and the values are those given in the original records, so that the value given for a high-priced commodity received in small quantity may not be strictly applicable to the quantity given. For instance, 2,705 pounds of cyanide received in 1916 is reported as 1 ton, but the value given is that of the actual quantity received. Furthermore the values are those placed on the commodities by the shippers, and represent the values at point of shipment and do not agree with market quotations in this country.

[b] Used principally in fertilizers. [c] Pounds. [d] Used principally in chemical industries.

[a] Used principally in fertilizers.

[b] Pounds.

[c] Used principally in chemical industries.

The first four salts listed in the foregoing table—kainite, manure salts, muriate and sulphate—are used principally in fertilizers. In 1913 they constituted about 94 per cent of the total potash imports, but in 1918 only 3.3 per cent. Kainite, the lowest-grade material imported, is a double sulphate and chloride of potassium and magnesium ($KCl.MgSO_4.3H_2O$) and theoretically contains 18.9 per cent of potash (K_2O). The product shipped is mixed with much sodium chloride and is sold with a guaranty of a minimum potash content of 12.4 per cent. It is sold as it comes from the mine without previous treatment for use in fertilizers. In 1913 nearly 24 per cent of the total potash imports came as kainite. Manure salts are essentially mixtures of potassium chloride, sodium chloride, and magnesium sulphate and are low-grade fertilizer materials. Several grades are produced which contain from 20 to 30 per cent of potash (K_2O). Nearly all material of this class, however, comes to the United States as the 20 per cent grade, and the small quantities of other grades imported are included in the table under manure salts. Before the war manure salts constituted about 18 per cent of the potash imported. In 1918 no kainite and no manure salts were imported. Muriate is a high-grade fertilizer material containing about 80 per cent of potassium chloride and 20 per cent of sodium chloride. In 1913 it constituted about 44 per cent of the total potash imported and in 1918 only 0.6 per cent. Although used largely in fertilizers, it is a raw material in the manufacture of many potassium compounds, notably caustic, carbonate, chlorate, perchlorate, and nitrate. Sulphate as usually imported contains about 90 per cent of potassium sulphate. It is used principally in fertilizers, especially for growing tobacco, but considerable quantities of it are used in chemical industries. In 1913 21,594 metric tons of muriate, equivalent to 10,905 metric tons of K_2O, and 643 metric tons of potassium sulphate, containing 313 metric tons of K_2O, were imported for chemical purposes.[1]

The other materials listed in the table of imports are manufactured potassium salts, more or less refined, and are used in chemical industries. In 1913 they made up about 6 per cent of the potash imports, and in 1918 96.7 per cent. Most of them are also manufactured in the United States and are described on pages 420–439. Imports in 1918 are classified in the following table as refined salts and crude salts:

[1] Federal Trade Commission report on fertilizer industry, 1916, p. 115.

Potassium salts imported and entered for consumption in the United States in 1918.

Potassium salts.	Quantity (short tons).	Value.
Refined salts:		
Bicarbonate	36	$34,279
Bitartrate	7	3,355
Carbonate	104	65,974
Chlorate	355	248,160
Chromate and bichromate	[a] 20	8
Cyanide	12	10,278
Ferricyanide	8	29,201
Ferrocyanide	65	112,729
Iodide	32	142,324
Nitrate	2	730
Permanganate	27	128,438
Rochelle salt	8	4,948
	656	780,424
Crude salts:		
Muriate	424	102,109
Sulphate	101	15,329
Bitartrate (argol)	14,041	4,782,267
Carbonate	4,297	2,273,202
Carbonate, black salts	228	47,956
Nitrate	4,672	906,549
	23,763	8,127,412
Grand total	24,419	8,907,836

[a] Pounds.

For many years practically all the potash imported came from Germany. During the war imports from various parts of the world represented both accumulated stocks and domestic production in those countries. In 1917 approximately 17 per cent of the imports came from Russia, 15 per cent from England, 14 per cent from Japan, 12 per cent from Chile, 11 per cent from Spain, 10 per cent from Italy, 9 per cent from France, 5 per cent from Portugal, 4 per cent from Argentina, and the remaining 3 per cent from other countries. About 35.5 per cent of the total came in the form of argol, cream of tartar, and Rochelle salt, which had previously not been included in the statistics of potash. Approximately 28 per cent of these commodities came from Italy, 26 per cent from France, 15 per cent from Spain, 12 per cent from Portugal, 10 per cent from Argentina, and the remaining 9 per cent from other countries.

In 1918 20.9 per cent of the potash imported came from Russia, 19.6 per cent from India, 12.4 per cent from Japan, 12.2 per cent from Italy, 11.4 per cent from Spain, and 23.5 per cent from 15 other countries. The imports in 1918 from various countries are shown in the following table:

Potash materials imported by the United States in 1918 in short tons.[a]

[a] The figures in this table were compiled from the records of the Bureau of Foreign and Domestic Commerce, United States Department of Commerce, by recalculation to short tons and to actual potash (K_2O) and by giving the totals by the calendar year instead of the fiscal year. The tons are calculated to the nearest even unit. The data represent general imports and include imports both for immediate consumption and those going to warehouses, which may or may not be entered for consumption during the year. They differ slightly from the figures in the preceding table of imports, which represent imports for consumption.

[b] Pounds.

Imports of the more important potassium salts for the years 1913 to 1918 are shown in the table on pages 391–392, which includes all the potassium salts listed in the records of the Bureau of Foreign and Domestic Commerce. Small quantities of other potassium salts imported are grouped with other commodities in customhouse office reports, so that data as to their quantity and value are not generally available. In a recent report, however, these data for the fiscal year ending June 30, 1914, have been made available and are shown in the following table:

Potassium salts imported and entered for consumption in the United States for the fiscal year ending June 30, 1914.[a]

Potassium compound.	Quantity (pounds).	Value.
Potassium (metal)	998	$330
Potassium acetate	528	108
Potassium aluminium sulphate (potash alum)	270,114	3,493
Potassium bicarbonate	478,903	22,783
Potassium bichromate	30,088	2,362
Potassium binoxalate	55,732	4,033
Potassium bisulphite (liquid, 30 per cent)	35,200	656
Potassium bisulphite (pure crystals)	185	16
Potassium bitartrate (pure crystals)	150,460	28,821
Potassium bromide	361	200
Potassium carbonate (crude black salts)	2,599,935	52,494
Potassium carbonate (crude)	9,042,754	239,691
Potassium carbonate (refined)	10,420,673	368,324
Potassium carbonate (chemically pure)	385	113
Potassium chlorate	40,480	3,503
Potassium chloride (pure white)	1,734,835	25,444
Potassium chloride (chemically pure)	25,015	1,115
Potassium chromate	4,205	460
Potassium chromium sulphate (chrome alum)	842,200	31,384
Potassium cyanide	808,721	113,199
Potassium ferricyanide (red prussiate)	90,007	15,350
Potassium ferrocyanide (yellow prussiate)	3,508,229	390,056
Potassium glycerophosphate	244	228
Potassium hydroxide (not in sticks)	8,395,049	320,753
Potassium hydroxide (refined, in sticks)	56,353	5,913
Potassium hypophosphite	300	130
Potassium iodate	62	153
Potassium iodide	169	491
Potassium iodometabisulphite	4,400	215
Potassium mercuric iodide	42	333
Potassium metabisulphite (liquid, 30 per cent)	120,147	6,070
Potassium metabisulphite (pure crystals)	3,620	488
Potassium metasulphite (commercial liquid)	9,521	574
Potassium metasulphite (pure)	224	37
Potassium nitrate (crude saltpeter)	3,546,580	115,344
Potassium nitrate (refined saltpeter)	367,640	20,368
Potassium nitrite (commercial)	109	20
Potassium nitrite (pure sticks)	305	104
Potassium oxalate (pure crystals)	107,060	9,108
Potassium oxalate (chemically pure)	289	64
Potassium perchlorate (purified crystals)	24,391	1,925
Potassium perchlorate (chemically pure)	64	18
Potassium permanganate	1,351,941	91,185
Potassium persulphate	236	920
Potassium phosphate (monobasic)	14	9
Potassium phosphate (dibasic)	4,179	990
Potassium phosphate (tribasic)	458	164
Potassium silicate (pure solution)	152,329	2,563
Potassium silicate (pure exsiccated)	231	43
Potassium sulphite (commercial liquid)	7,626	404
Potassium sulphite (commercial powder)	11,252	1,833
Potassium sulphite (pure powder)	750	351
Potassium sulphocyanide	9,035	1,578
Potassium titanium oxalate	77,238	10,146
	44,391,866	1,896,457

[a] Pickrell, E. R., Chemicals and allied products used in the United States: U. S. Dept. Commerce, Bur. Foreign and Domestic Commerce, Misc. Ser. 82, 1919. The table includes salts imported primarily for chemical purposes. For other imports see pages 391–392.

In addition to the potassium salts listed in the preceding table and on pages 391–392, the following potassium salts were imported in 1914 in quantities valued at less than $100:

Potassium acridin, aluminate, ammonium chromate, potassium and iron tartrate, antimonate, antimony nitrate, arsenate, arsenite, benzene sulphonate, benzoate, benzo sulphoacid, benzol disulphonate, bifluoride, biiodate, biphosphate, bisulphate, borfluoride, bromate, butyrate, butylsulphate, cacodylate, chlorate of potassium and cocaine, chlorate of potassium and cocaine pastilles, chlorate and cocaine and soda borate, chloride and borax, citrate, cobalt cyanide, copper chloride, copper cyanide, cyanate, cyanide sodium, ethyl, ethyl sulphate, ethyl sulphonate, ferri oxalate, fluoreseinate, fluoride (purified), formate, gold chloride, hydrogen sulphate, hydrogen sulphide, hypophosphite, iodide strong paper, iodite, iron citrate, iron oxalate, iron sulphate, lactate, magnesium chloride, magnesium sulphate, methylsulphate, monosulphide, myronate, nitrite (pure crystals), nitro bisulphate, nitro prusside, oleate, percarbonate, periodate, phenate, phenolsulfonate para, phthalamide, pyroantimonate, pyrogallate solution, pyrophosphate, pyrosulphate, saccharate, salicylate, silicofluoride, sodium, sodium chloride, sodium sulphate, sodium urate, stannate, sulphide, telluride, tellurite, thiocyanate, tungstate purified, xanthogenate, zinc chloride.

EXPORTS.

A comparatively small quantity of potash is exported by the United States, and the statistics are far from complete. The available data are summarized in the following table:

Potassium salts exported from the United States, 1914, 1917, and 1918.

Potassium salt.	1914[a]		1917[b]		1918

[b] Covers period from July 1 to Dec. 31, 1917.
[c] Quantity not available.
[d] Included in "All others."

PRICES.

Before the European war the most efficient German potash mines could produce 80 per cent muriate containing an equivalent of 50 per cent of potash (K_2O) at about $15 a ton and kainite containing a guaranteed minimum of 12 per cent of potash at less than $2 a ton at the mines. Shipping and other costs amounted to about $3 to $5 a ton. These low costs are illustrated by the prices given in the so-called

Schmidtmann contracts with several American fertilizer companies in 1909. The contracts covered a period of two years with the privilege of renewal for five years more and called for deliveries of not less than 27,000 tons of potash (K_2O) annually. The Schmidtmann mines, which were among the most efficient in Germany, could probably have operated at these prices, although most of the other German mines could not. The following table shows the Schmidtmann prices and in comparison the prices that were afterward established by the German potash syndicate:

Wholesale prices per short ton of potash salts c. i. f. Atlantic ports, 1910.[a]

Potash salt.	Approximate percentage of potash (K_2O) content.	Schmidtmann prices, 1910.				Syndicate prices, January–June, 1910.			
		Price f. o. b. mines.	Additional charges.[b]	Net price c. i. f. Atlantic ports.	Net price per unit of K_2O.	List price.	Three per cent discount.	Net price.	Approximate net price per unit of K_2O.
Sulphate	48.6	$20.94	$4.86	$25.80	$0.53	$40.00	$1.20	$38.80	$0.80
Muriate	50.0	15.54	4.86	20.40	.41	34.00	1.02	32.98	.66
Manure salts	20.0	3.89	3.24	7.13	.36	12.00	.36	11.64	.58
Hartsalz	16.0	2.48	3.24	5.72	.36	9.00	.27	8.73	.55
Kainite	12.4	1.92	3.24	5.16	.42	7.27	.22	7.03	.57

[a] Federal Trade Commission report on the fertilizer industry, 1916, p. 155.
[b] Includes bagging, insurance, and freight, from mines to Atlantic ports.

In 1910 list prices were increased, but discounts were graded so that for quantities in excess of 20,000 tons of potash (K_2O) they amounted to 15 per cent on muriate, sulphate, and other concentrated salts, and to 15.5 per cent on crude salts (kainite, hartsalz, and 20 per cent manure salts). These prices are shown in the following table:

Wholesale prices per short ton of potash salts c. i. f. Atlantic ports, 1911–1914.[a]

Potash salt.	Approximate percentage of potash (K_2O).	1911–1913			1914 [b]			
		List price.	Discount.[c]	Net price.	List price.	Discount.[c]	Net price.	Approximate net price per unit of potash (20 pounds of K_2O).
Sulphate	48.6	$46.30	$6.95	$39.35	$47.58	$7.14	$40.43	$0.83
Muriate	50.0	38.05	5.71	32.34	39.07	5.86	33.21	.66
Manure salts	20.0	13.30	2.06	11.24	13.58	2.10	11.48	.57
Hartsalz	16.0	10.65	1.65	9.00	10.87	1.68	9.19	.57
Kainite	12.4	8.25	1.28	6.97	8.36	1.30	7.06	.57

[a] Federal Trade Commission report on the fertilizer industry, 1916, p. 155.
[b] These prices, which were for January to June, 1914, were increased slightly during the latter part of the year. See Oil, Paint, and Drug Reporter, vol. 85, p. 59, 1914.
[c] 15 per cent discount on sulphate and muriate and 15½ per cent on 20 per cent manure salts, hartsalz, and kainite.

As will be observed from the table, net prices to large importers varied from 57 cents per unit (20 pounds of K_2O) for the lowest-

grade product to 83 cents for sulphate. The list prices, which are generally shown in market quotations in the United States, correspond to 67 cents per unit for the low-grade material and 98 cents for sulphate. Ocean freight rates to the United States on these salts in bulk from Hamburg averaged about $2 per metric ton to northern ports and $2.50 to $2.90 to southern ports.

After the embargo of January 30, 1915, placed on the exportation of potash salts from Germany, the prices of these salts rose rapidly. Early in 1915, market quotations on 80 per cent muriate were around $115 a ton and gradually rose to $500 a ton in December. The quotations in 1916 varied from $300 to $490 a ton, in 1917 from $325 to $450 a ton, and in 1918 from $260 to $350 a ton. These quotations are not indicative of the actual selling price of potash materials, as only limited quantities of muriate were on the market and muriate was at a premium because of its use as a raw material in the manufacture of various refined potassium salts. The actual selling price in the eastern markets of the domestic output was about $4.87 per unit in 1916, $4.79 in 1917, and $4.61 in 1918. These data are shown in the following table. Prevailing prices of the various potassium compounds are discussed under the individual potassium salts, pages 420–439.

Wholesale price of potash in the United States 1915–1918.

Year.	Market quotations of 80 per cent muriate.[a]						Approximate average selling price per unit of K_2O of domestic output.	
	Per short ton of salt.			Per unit of K_2O.			F. o. b. plant.	Eastern markets.
	High.	Low.	Average.	High.	Low.	Average.		
1915	$500	$115	$245	$10.00	$2.30	$5.90	$3.14	$3.64

[a] Quotations for 1915 and 1916 taken from Jour. Ind. and Eng. Chemistry, and for 1917 and 1918 from Oil, Paint, and Drug Reporter.

USES.

Potash is used principally as a fertilizer, particularly in growing cotton, potatoes, tobacco, citrous fruit, and garden truck. It is applied extensively to thin sandy soils in Germany, the United States, Holland, France, and a few other countries. In 1913 more than 90 per cent of the world's production was thus consumed. The centers of consumption in the United States are mainly in the Southeastern States and along the Atlantic seaboard. Potash, in the form of refined potassium salts, is also used in the manufacture of soap, glass, matches, explosives, and pyrotechnics, medicines, for extracting gold from its ores, in dyeing, tanning, electroplating, photography, and as chemical reagents. The uses of the various salts are discussed under the individual potassium salts on pages 420–439.

POTASH IN RELATION TO THE WAR.

When German supplies of potash were cut off in 1915 accumulated stocks in the United States were sufficient to meet a large part of the needs for that year. Thereafter only small quantities of German potash could be had outside of the Central Powers, and the rest of the world was forced to produce its own supply of potash or else to get along without it. Prices advanced rapidly and were maintained during the war at about six times their normal level. These high prices stimulated production throughout the world. Russia produced considerable quantities of carbonate from wood ashes and sunflowers, India increased her shipments of nitrate, in the Chilean nitrate industry considerable quantities of potassium nitrate were recovered as a by-product, Japan produced potash from several different sources, and many other countries produced more or less potash. But by far the greatest developments took place in the United States.

In 1910 the United States began investigations looking toward a domestic supply. In 1914 when the war broke out in Europe, the potash deposits of Searles Lake, Calif., and of the Nebraska lakes, the alunite deposits of Utah, the kelp beds of the Pacific coast, the leucite rocks of Wyoming, and the greensand deposits of New Jersey were all known and had received more or less attention. No production had been reported, however, and no potash plants had been installed. The potash industry of the United States had its beginning in 1914, when American Potash (Inc.), of Long Beach, Calif., made a small production from kelp. This was a direct outgrowth of the European war. In 1915, 1,090 short tons of actual potash was produced. Thereafter the number of sources increased and the production rose rapidly. The developments are briefly summarized in the table on page 386. Among the most important new sources developed during the war are the by-product sources—cement plants, blast furnaces, molasses distilleries, and beet-sugar refineries—which are capable of yielding a large part of our domestic needs and which appear to offer the best possibility of development on a basis of permanent competition. The supply of potash in the United States was normal in 1914, and probably half the normal supply was available in 1915. Imports and production amounted to 17,605 tons in 1916, 40,673 tons in 1917, and 62,760 tons in 1918.

The curtailment of potash in fertilizers in Allied countries and especially in the United States during the war was a serious handicap in the production of cotton, tobacco, potatoes, garden truck, and certain other crops, while its increased consumption in Germany and Austria aided those countries greatly in the production of food.

Potassium nitrate is an essential constituent of all black powder, approximately 11,500,000 pounds of which were manufactured for the Ordnance Department during the war. For military purposes black powder containing about 74 per cent of potassium nitrate is used (1) as an ignition charge for igniting the propellant charge of smokeless powder, (2) as a base charge for expelling shrapnel shell, (3) in the manufacture of primers and fuses, (4) in saluting and blank fire charges, (5) in time train rings and combination fuses,

and (6) in mixtures with other kinds of powders for use in small arms ammuntion. Potassium nitrate is also used to a minor extent in the preparation of pyrotechnics.

Potassium chlorate is used extensively in the preparation of primers, caps, and detonators in combination with fulminate of mercury. Approximately 245,250 pounds was used by the United States for this purpose during the war, and a considerable supply was accumulated for expected use.

Very pure potassium carbonate is an essential raw material in the manufacture of optical glass, which was produced in the United States on a large scale during the war for use in searchlights, reflectors, field glasses, and optical instruments of all kinds. The optical glass industry, which was an outgrowth of the war, experienced much difficulty in obtaining supplies of potassium carbonate suitable for its purpose and depended, at first, on small reserve stocks until domestic firms were able to meet the demand.

Certain other potassium salts found some application during the war, as, for instance, small quantities of potassium perchlorate were used in explosives and pyrotechnics, and pure crystals of Rochelle salt (potassium sodium tartrate) were used for their electrical properties in detectors and sound amplifiers.

CRISIS IN THE AMERICAN POTASH INDUSTRY.

When the armistice was signed in November, 1918, only a few large producers in the United States had made their original investments out of the potash industry, many plants had been operated only a short time, and others were under construction. About one-third of the potash produced in 1918 was still in the hands of producers, money for operating expenses had been advanced on the potash held in storage, and developments had gone forward under the prevailing price of $4 to $5 per unit of potash. Anticipation that low-priced potash from foreign sources would be available followed the armistice agreement, checked sales of domestic potash, and caused the price to fall to about $2.50 per unit—a price lower than the cost of production of many producers. These conditions caused a crisis in the potash industry, and producers began to close their plants. By the early part of 1919 nearly all producers had shut down and some had gone out of business.

DISTRIBUTION OF POTASH IN NATURE.[1]

Potash is widely disseminated in nature, occurring in rocks, soils, saline residues, the ocean, the waters of rivers and lakes, and the tissues of plants and animals. It is an essential constituent of the rock-forming minerals feldspar, orthoclase, mica, leucite, nephelite, and glauconite, and it constitutes 2.99 per cent of igneous rocks, 3.24 per cent of shales, 1.31 per cent of sandstones, 0.48 per cent of soils, and 0.33 per cent of limestones, and averages 2.98 per cent of the entire crust of the earth. Enormous deposits of potash-rich silicate rocks occur in the United States, Italy, and elsewhere. The potash reserves in a number of such deposits in the United States are indicated on pages 408–409.

[1] Compiled largely from Clarke, F. W., The data of geochemistry, 3d ed.: U. S. Geol. Survey Bull. 616, 1916.

Although silicate rocks contain potash in an insoluble combination and in a form which is not available for industrial use, they are gradually decomposed on exposure to the weather. The potash, thus rendered soluble, is dissolved by rain or ground water, and it finally reaches the ocean or inclosed drainage basins through streams or is absorbed from percolating water by clays.

River waters of North America contain an average of 281 parts per million dissolved salts, of which an average of 1.77 per cent is potassium. They carry annually to the ocean 8,339,800 metric tons of potassium, and the river waters of the world carry 57,892,000 metric tons. The annual precipitation of potassium in insoluble form in the ocean is 50,320,000 metric tons, leaving an annual gain of potassium by the ocean of 7,662,000 metric tons. The total potassium content of the ocean is 510,800,000,000,000 metric tons. Ocean water contains 3.30 per cent of salts, of which 1.11 per cent is potassium, corresponding to 1.38 per cent of potash (K_2O).

Practically all salt deposits contain potash, but generally in very small quantity. Some salt deposits are unusually rich in potash, and they furnish practically the entire world's output. The principal known deposits are those in Germany, Alsace, Spain, Galicia, Abyssinia, Searles Lake, Calif., and Nebraska. Estimates place the potash (K_2O) in the deposits in Germany at 2,000,000,000 tons, in Alsace at 300,000,000 tons, in Searles Lake at 20,000,000 tons, and in the other deposits at much smaller quantities. The approximate potash content of these deposits according to present knowledge is shown in the following table:

Potash reserves in commercial deposits.

	Character of raw material.	Approximate percentage of potash (K_2O) in the crude dried salts.	Potash in reserve in tons of K_2O.
Germany	Salt	15	2,000,000,000
Alsace	do	22	300,000,000
Searles Lake, Calif.	Brine	7	20,000,000
Spain	Salt	15	[a] 30,000
Nebraska	Brine	25	[a] 00,000
Abyssinia	Salt	24	[a] 200,000
Galicia	do	10	[a] 40,000

[a] Estimate indefinite and inconclusive.

POTASH FROM SALINES.

NEBRASKA LAKES.

Nebraska lakes furnished by far the largest output of potash from a single source in 1918. The production amounted to 116,662 short tons of crude material containing 28,854 tons of potash (K_2O). This quantity represented 53 per cent of the total domestic output of potash (K_2O) and approximately twice the production from Nebraska in 1917. The sales in 1918 amounted to 57,522 tons of crude salts, containing 14,011 tons of potash (K_2O), valued at $5,098,023. The value corresponds to an average of $4.11 per unit at point of shipment, compared with $4.04 per unit in 1917. The prod-

uct marketed consisted of the solids obtained by evaporating the brine and contained from 20 to 28 per cent of potash (K_2O), or an average of nearly 25 per cent. Nineteen companies reported production. Eight of these are located on the Chicago, Burlington & Quincy Railroad and have capacities ranging from about 50 to 200 short tons of crude potash a day. Four large plants, which reported production in 1917 were practically in continuous operation throughout the year. Of four additional large plants, one was in operation about six months, and the three others only for a short time. Eleven small plants are located from 3 to 15 miles from the railroad and have capacities ranging from 3 to 10 tons of crude salts a day. Three of these plants were in operation throughout the year and eight were in operation for only a few months.

The quantity of potash in the Nebraska field is not known. The brines are obtained for the most part at a depth of about 12 feet from sands underlying small lakes scattered through an area of about 800 square miles in the sand-hill region. Those so far worked contain from 2 to 15 per cent of solids. The productive area under the lakes varies greatly. It underlies a large part of some lakes, but usually only a small portion of the subsurface sands contain commercial brines. Explorations are made by sinking wells beneath the surface waters, which is rather difficult and often unsatisfactory and inconclusive. Furthermore, a few wells sunk in valleys at some distance from the lake have encountered brines that might be considered commercial, the quality indicating that the productive area might possibly extend far beyond the lakes themselves and even in some localities where there are no lakes. Under these conditions an estimate of the quantity of commercial potash brines in the Nebraska region is not only very difficult but exploration has not yet extended far enough to make any estimate conclusive. Early in 1918 Condra[1] thought that productive brines would be greatly reduced in four years if the rate of production at that time was continued. This estimate corresponded probably to a total output of 100,000 tons of potash (K_2O). Other estimates have varied greatly. From a study of the whole region in which the productive area of all the known potash lakes and the composition of the brines are taken into account it seems probable that the Nebraska lakes contain several hundred thousand tons and possibly half a million tons of actual potash in brines that run 1 per cent or higher in salts. This quantity would probably keep the plants now constructed in operation for 10 years.

The following firms produced potash from the Nebraska field in 1918:

Acme Potash Co., Antioch, Nebr.
Alliance Potash Co., Antioch, Nebr.
American Potash Co., Antioch, Nebr.
Byrn Potash Co., Antioch, Nebr. (now owned by the Omaha Potash & Refining Co.).
Great Northern Potash Co., Antioch, Nebr.
Home Potash Co., Alliance, Nebr.
Hord Co., Lakeside, Nebr.

[1] Condra, G. E., Preliminary report on the potash industry in Nebraska: Nebraska Conservation and Soil Survey Bull. 8, p. 36, 1918.

Liberty Potash Co., Antioch, Nebr.
Lincoln Potash Co., Antioch, Nebr.
National Potash Corp., Antioch, Nebr.
Nebraska Potash Works Co., Antioch, Nebr.
Nebraska-Wyoming Potash Co., Antioch, Nebr.
Omaha Potash & Refining Co., Lakeside, Nebr.
Pioneer Potash Co. (formerly Wilson Potash Co.), Antioch, Nebr.
Potash Reduction Co., Hoffland, Nebr.
Robbins Potash Works, Antioch, Nebr.
Rogers, Smith Potash Co., Antioch, Nebr.
Standard Potash Co., Lakeside, Nebr.
Western Potash Works, Antioch, Nebr.

Companies with plants under construction at the close of 1918 were:

Fenner Potash Co., Alliance, Nebr.
Hawkeye Potash Co., Antioch, Nebr.
Pioneer Potash Co. (formerly Wilson Potash Co.), Antioch, Nebr.
William Berg Co., Merriman, Nebr.

Two companies constructed plants which were shut down after a short run. These were the Burnham Potash Co., Antioch, Nebr., and the Commonwealth Potash Co., Birdsell, Nebr.

SEARLES LAKE, CALIF.

Searles Lake, Calif., furnished the second largest output of domestic potash from a single source in 1918, the production being nearly double that in 1917. Most of the product contained from 60 to 70 per cent of potassium chloride and about 15 per cent of borax. In the process of manufacture the brine, after partial evaporation to remove a part of the associated salts, is drawn off and allowed to cool, when the commercial product is deposited. A portion of this material is refined to produce high-grade muriate, but most of it has been marketed as of lower grade. The plant of the American Trona Corporation, at Trona, and that of the Solvay Process Co. at Borosolvay, were in operation practically throughout 1918. The capacity of these plants at the end of the year was estimated at 25,000 tons of potash (K_2O) a year. No other plants had been built and none were under construction in 1918.

After the settlement of the controversy concerning the claims of the American Trona Corporation and the promulgation of the potash leasing law in the later part of 1917,[1] that portion of the Searles Lake potash fields which was not owned by nor awarded to the two operating companies, embracing nearly 16,000 acres, was divided into 11 leasing districts. These subdivisions were taken up by various interests, some of which made plans to construct plants for the utilization of the brines, but no actual construction took place.

Estimates indicate that Searles Lake contains the equivalent of 20,000,000 tons of actual potash (K_2O) in a saturated brine associated with soda, borax, salt, and sodium sulphate. The proportion of potash in the dried salts is about 7.2 per cent. The proceesses of extraction are still undergoing changes and so far have not included the manufacture of by-products. Freight rates to eastern markets are much higher than those from foreign deposits. More-

[1] An act to authorize exploration for and the disposition of potassium: 40 Stat., 297; Potash regulations; Dept. Interior Circ. 594.

over, the potash (K_2O) content of the German and Alsatian deposits ranges from 12 to 20 per cent, the processes of extraction are firmly established, and the cost of production is low. These facts lead to the belief that production at Searles Lake at competitive prices is limited by and is contingent upon the development both of technical processes for the recovery of by-products and of a market for these by-products at profitable prices and upon the removal of the serious handicap of high freight rates, either by rail or boat, to distant markets located in the Eastern and Southern States.

GREAT SALT LAKE, UTAH.

Two companies produced potash salts from the brines of Great Salt Lake, Utah, in 1918, but their combined output was small. The plant of the Utah Chemical Co. is at Potash siding, on the branch of the Salt Lake Route running from Salt Lake City to Saltair. It was designed to recover potash as a by-product in the manufacture of salt. The plant of the Salt Lake Chemical Co., a subsidiary of the Diamond Match Co., is at Grantsville, about 30 miles west of Salt Lake City, on the Western Pacific Railroad. It was designed to handle the lake water primarily for its potash content. The general nature of the operations of these companies was described in the report on potash in Mineral Resources for 1916.

SALDURO MARSH, UTAH.

The Solvay Process Co. produced potash from Salduro Marsh, Utah, in 1918. The product consisted of muriate containing an equivalent of about 42 per cent of potash (K_2O). Being practically free from carbonates and sulphates and containing magnesium salts, the potash brines of Salduro are similar in type to the artificial potash brines of the German potash works. Although the exact process adopted by the company at Salduro is not disclosed, it is presumed to be similar to the refining processes used in Germany. No estimate of the potash reserve in Salduro Marsh is available, but the quantity is believed to be small. The Solvay Process Co. transferred its interest at the end of 1918 to the Utah-Salduro Potash Co., a subsidiary, and no other developments have been recorded.

SEA-WATER BITTERNS.

The Oliver Chemical Co., Mount Eden, Calif., and the Whitney Chemical Co., San Mateo, Calif., each reported a small production of potash from sea-water bitterns in 1918. The product contained from 12 to 45 per cent of potash (K_2O). Several plants on the Pacific coast produce salt from sea water, and the residual mother liquor contains from 2 to 8 per cent of potash (K_2O). The quantity of such liquor available for the production of potash is not known, but is believed to be too small to yield a large output.

MISCELLANEOUS.

The United Mineral Products Co. produced a small quantity of crude potash in 1918 from brine obtained by sinking shallow wells into the dry bed of an old lake near Hartsell, Colo. Apparently the flow of brine is weak and the supply is meager.

A general summary of explorations for potash was included in the report for 1917. Explorations in 1918 have not revealed any new sources of supply and have not resulted in any extensive developments.

POTASH FROM ALUNITE.

Potash materials produced and sold from alunite in 1918 amounted to 6,180 short tons containing 2,621 tons of potash (K_2O), valued at $1,276,774 at the point of shipment, or at $4.87 per unit of K_2O. The quantity represented 5 per cent of the total domestic production of potash (K_2O), and was a slight increase over the production from alunite in 1917. The product consisted for the most part of high-grade sulphate containing about 51 per cent of K_2O. Small quantities, both of alum containing about 10 per cent K_2O and of calcined alunite containing from 4.5 to 13 per cent of K_2O, were also produced and shipped. The entire output came from the alunite deposits in the vicinity of Marysville, Utah. Four companies reported production from this field in 1918. One company produced high-grade sulphate, one produced alum, one produced calcined alunite at the Florence calcining plant at Marysville, and one shipped raw alunite to Harvey, La., for calcining.

The most important developments in 1918 consisted in the completion at Marysvale of the plant of the Mineral Products Corporation, which had burned in the later part of 1917; the construction of a plant for the manufacture of alum from alunite at Murray, Utah, by the American Smelting & Refining Co.; and the building of a calcining plant for the treatment of alunite at Harvey, La., by Swift & Co.

The quantity of alunite available for potash is not known. Estimates place the quantity in one group of claims to a depth of 100 feet at 475,000 tons and indicate the probable depth of the deposit at 1,000 feet.[1] The quantity of alunite of good quality in other claims is largely a matter of conjecture.

Production of potash from Marysvale, Utah, in 1918 was reported by the following companies:

American Smelting & Refining Co., Murray, Utah.
Caraleigh Phosphate & Fertilizer Works, Raleigh, N. C.
Mineral Products Corporation, Marysvale, Utah.
Swift & Co., Harvey, La.

Considerable exploration and development work was done in 1918 on the alunite claims at Sulphur, Nev., and Rico, Colo., but no production was reported from these properties.

POTASH FROM BLAST FURNACES.

Four steel companies—the Bethlehem Steel Co., South Bethlehem, Pa.; the Carnegie Steel Co., Pittsburgh, Pa.; the Thomas Iron Co., Hokendauqua, Pa.; and the Tennessee Coal, Iron & Railroad Co., Birmingham, Ala.—marketed potash materials from blast-furnace dust in 1918. Most of the product contained from 6 to 9 per cent of water-soluble potash (K_2O) and represented merely the dust that settled in the stoves and boiler flues, where the blast-furnace gases are finally consumed. A small quantity of potassium sulphate was also produced.

[1] Loughlin, G. F., Recent alunite developments near Marysvale and Beaver, Utah: U. S. Geol. Survey Bull. 620, pp. 237–270, 1916.

The present estimates of the recoverable potash from blast-furnace gases are based on inconclusive evidence and range from 50,000 to 200,000 tons of potash (K_2O) annually. Plants now being installed are expected to demonstrate the commercial feasibility of saving the potash from this source. Cottrell dust-collecting systems for recovery of potash are being built at the plant of the American Manganese Manufacturing Co., Dunbar, Pa., and the Lochiel furnace, Harrisburg, Pa.

POTASH FROM CEMENT MILLS.

Potash materials produced as a by-product in the manufacture of cement in 1918 amounted to 12,652 short tons containing 1,549 tons of potash (K_2O). This quantity represented 3 per cent of the total output of potash in the United States and was a slight decrease from that reported in 1917. The sales amounted to 11,172 tons of potash materials containing 1,366 tons of potash (K_2O), valued at $539,567. The product marketed consisted of about equal parts of dust containing 2 to 10 per cent of potash and of potassium sulphate containing 25 to 62 per cent of potash. Twelve cement mills reported production in 1918. Seven of these mills had installed potash-recovery plants, including leaching and evaporating systems, and marketed potassium sulphate. Four mills had installed dust-collecting systems and marketed cement dust for incorporation into fertilizers. One mill had installed no potash plant but marketed a small quantity of dust that had collected in the flues and under the stacks.

The 11 cement mills with potash-recovery plants which reported production of potash in 1918 produced 6,165,000 barrels of cement, from which 6,560 tons of potash K_2O were recoverable. Seven of these mills were in operation throughout the year except when shut down from lack of fuel, or because of alterations or repairs, and four were in operation only a short time.

Developments in 1918 included putting into operation four new potash-recovery plants in cement mills, practical completion of construction of plants in five mills, beginning of construction in two other mills, and installation of waste-heat boilers in connection with potash-recovery plants in some mills.

About 110 cement mills in the United States produce annually about 90,000,000 barrels of cement, 70 per cent of which comes from Eastern States contiguous to large centers of consumption of potash. Estimates place the potash recoverable as a by-product in the cement industry at about 75,000 tons of K_2O annually.

Cement manufacturers which reported production of potash in 1918 are as follows:

Alpha Portland Cement Co., Cementon, N. Y.
Atlas Portland Cement Co., New York, N. Y.
California Portland Cement Co., Colton, Calif.
Coplay Cement Manufacturing Co., Coplay, Pa.
Dexter Portland Cement Co., Nazareth, Pa.
Newaygo Portland Cement Co., Newaygo, Mich.
Ogden Portland Cement Co., Ogden, Utah.
Portland Cement Co,. of Utah, Salt Lake City, Utah.
Riverside Portland Cement Co., Riverside, Calif.
Santa Cruz Portland Cement Co., Davenport, Calif.
Security Cement & Lime Co., Hagerstown, Md.
Southwestern Portland Cement Co., Victorville, Calif.

At the end of 1918 potash-recovery plants were under construction by the following cement mills, the first three being practically completed:

Clinchfield Portland Cement Corp., Kingsport, Tenn.
Ironton Portland Cement Co., Ironton, Ohio.
Louisville Cement Co., Sellersburg, Ind.
Aetna Portland Cement Co., Fenton, Mich.
Peninsular Portland Cement Co., Cement City, Mich.

POTASH FROM SILICATE ROCKS.

Potash materials were produced from greensand in 1918 by two experimental plants—one producing caustic potash and the other muriate. The actual production was small, and the figures are included with those from blast furnaces. The producing companies were the Eastern Potash Corporation (formerly the Kaolin Products Corporation), Jones Point, N. Y., and the Atlantic Potash Co., Stockertown, Pa. A description of the operations of these companies was included in the report for 1917.

R. S. Ryan & Co. constructed a commercial plant at Reeves station, near Medford, N. J., for the extraction of potash from greensand by the Tschirner process.[1] The Liberty Potash Co. built a plant at Green River, Wyo., said to have cost $1,000,000, for the extraction of potash from leucite rocks by the Boyer-Sterling process,[2] and the National Process Co., which is affiliated with the Louisville Cement Co., began construction of a plant at Louisville, Ky., for the extraction of potash from shales. The Georgia Potash & Chemical Co. acquired a large acreage of the Georgia shales and control of the Cottrell patents as applied to Southern States. Other companies have been active and considerable experimental work has been done, but so far as known to the United States Geological Survey, no other commercial plants were under construction at the end of 1918.

Among the raw materials to be considered in connection with the extraction of potash from silicate rocks are the deposits of greensand[3] (glauconite) in New Jersey, Delaware, and Maryland, which carry about 7 per cent of potash; the feldspar deposits from Maine to North Carolina;[4] the potash-bearing rocks of the Leucite Hills in Sweetwater County, Wyo.,[5] which carry about 10 per cent of potash; sericites and slates of Georgia, said to contain about 9 per cent of potash;[6] and the tailings[7] collected in certain dumps at copper and gold mines in the West, which carry probably from 5 to possibly as much as 10 per cent of potash. Feldspar often contains from 10 to 14 per cent of potash (K_2O), but a series of analyses (unpublished) by the United States Geological Survey indicates that the average quarry product rarely contains more than 7 to 7.5 per cent.

[4] Bastin, E. S., U. S. Geol. Survey Bull., 420, 1910. Watts, A. S., Bur. Mines Bull. 53, 1913; Bull. 92, 1916.
[5] Schultz, A. R., and Cross, Whitman, Potash-bearing rocks of the Leucite Hills, Wyo.: U. S. Geol. Survey Bull. 512, 1912.
[6] McCallie, S. W., Eng. and Min. Jour., vol. 104, p. 643, 1917. Also Shearer, H. K., The slate deposits of Georgia: Georgia Geol. Survey Bull. 34, 1918.
[7] Butler, B. S., Potash in certain copper and gold ores: U. S. Geol. Survey Bull. 620, pp. 227–236, 1916.

No estimates of quantity for feldspar and sericite are available, but the quantity of these materials is known to be very large. Washington[1] estimates the potash in the greensands of New Jersey at 2,034,000,000 metric tons. Schultz and Cross estimated the potash in the Leucite Hills of Wyoming at 197,000,000 tons. Butler's figures indicate that in 1914 more than 100,000,000 tons of mill tailings had accumulated in the dumps at copper and gold mines, and that many hundred million tons of unmined ore had been developed. These data are sufficient to show the magnitude of the supply of this class of raw materials.

Many processes have been devised for the extraction of potash from silicate rocks, some of which have been subjected to experimental tests. United States patents covering such processes were listed in the annual report on potash for 1917. Those granted in 1918, and also foreign patents for 1918, are listed below. Printed copies of United States patents may be obtained from the United States Patents Office for 5 cents each.

United States patents for processes for extracting potash from silicate rocks.

1253560, Jan. 15, 1918, Anderson, E. L. Feldspar is mixed with carbon and electrolized in a solution of H_2SiF_6 to produce KOH.

1254450, Jan. 22, 1918, Tschirner, F. Glauconite is subjected to an oxidizing roast with CaO and $Ca(OCl)_2$ and leached to produce KCl.

1254451, Jan. 22, 1918, Tschirner, F. Greensand marl, lime sand, and calcium chloride are roasted at about 800° C. to convert the potassium into soluble form.

1254676, Jan. 29, 1918, Glaeser, W. Glauconite, calcium chloride, and coke, or similar materials, are heated to drive off combined water (270°) and the dry mixture then heated to about 800° C. in a nonoxidizing atmosphere to produce KCl and the silicate of iron and calcium.

1254677, Jan. 29, 1918, Glaeser, W. Feldspar, or other potash-bearing silicate, is mixed with an equal quantity of calcium chloride and about 5 per cent of FeO. It is then dried and heated to about 900° C. in a nonoxidizing atmosphere to produce KCl.

1256295, Feb. 12, 1918, Charlton, H. W. Feldspar is mixed with calcium carbonate in water in the proper proportion and heated under pressure above 200 pounds per square inch to convert the potassium into soluble form and to leave the insoluble residue suitable for the manufacture of a steam-hardening cement.

1260944, Mar. 26, 1918, Rody, F. A. Silicates, such as feldspar and leucite, are fused and reduced to a fine powder and then digested for about an hour with milk of lime under pressure, to bring the alkali into soluble form.

1263705, Apr. 23, 1918, Rody, F. A. Feldspar, leucite, or other similar silicate is heated to a sintering temperature with CaO and Na_2CO_3 and the product is boiled with water to dissolve the alkali.

1264572, Apr. 30, 1918, Sterling, G. Potash-bearing silicates are heated to about 1,400° C. with lime and the mother liquor salts from salt brines, and the potassium salts are sublimed and condensed.

1264949, May 7, 1918, Lindblad, A. R. Powdered feldspar, or other potash-bearing silicate, is mixed with carbon and lime and fused in an electric furnace. A part of the potash forms potassium cyanide and a part is volatilized and afterward collected.

1268508, June 4, 1918, Sterling, G. Feldspar or other potash-bearing silicate, mixed with calcium carbonate and sodium sulphate, is heated to a temperature just below vitrification and K_2SO_4 is sublimed and condensed.

[1] Washington, H. S., Italian leucite lavas as a source of potash: Met. and Chem. Eng., vol. 18, p. 71, 1918.

1270515, June 25, 1918, Haslup, E. W., and Peacock, B. A. Potash-bearing silicate rock and phosphate rock are treated with H_2SO_4 in a closed vessel at a temperature of from 200° to 300° C., and the residue lixiviated with water and the solution neutralized with alkali metal carbonate or hydroxide and the potassium and phosphorus compounds finally recovered by crystallization.

1277773, Sept. 3, 1918, Swenarton, W. H. Powdered feldspar is fused with K_2CO_3 at 800° to 1,200° C. for an hour, and the pulverized melt is digested with hot water and after separating the alumina the potassium salt is finally obtained by crystallization.

1279145, Sept. 17, 1918, Peacock, B. A. Powdered glauconite is heated with a slight excess of $Al_2(SO_4)_3$ to a temperature of from 200° to 250° C. to form K_2SO_4 and the latter is recovered by extraction with water.

1279109, Sept. 17, 1918, Haslup, E. W., and Peacock, B. A. Powdered greensand and bauxite are mixed with sulphuric acid and allowed to stand from 24 to 48 hours in a closed vessel, and the sulphates thus formed are extracted with water and alum is finally crystallized from the solution.

Canadian patents for processes for extracting potash from silicate rocks.

170834, July 18, 1916, Peacock, S. A silicate is melted in a closed furnace and a sufficient quantity of alkali is added to react with all the silicate to form a soluble alkali silicate.

174119, Dec. 26, 1916, Heyman, A. W. Alkali silicates are heated with a calcareous material until practically free from chloride and then leached with water through which carbondioxide is passed.

174704, Jan. 30, 1917, Frazer, J. C. W., and Mitler, E. The silicate is treated with caustic alkali so that a portion of the silica is removed as a soluble alkali silicate leaving a residual silicate readily decomposable by mineral acid.

176939, May 8, 1917, Blumenberg, H., jr. A process of extracting potassium from minerals by heating powdered feldspar mixed with an equal part of sodium nitrate to a temperature from 1,200° to 1,500° C. in a closed vessel until the liberation of nitric acid ceases and then treating the cooled groundmass with mineral acids.

179629, Oct. 9, 1917, Hone, A. D. Silicates are decomposed by using a fluoride and an acid and the potash is finally separated as potassium sulphate.

183238, Mar. 26, 1918, Swenarton, W. H. Finely ground feldspar is fused with K_2CO_3 at 800° to 1,200° C. and the cooled mass ground and digested with water which dissolves the potassium.

186421, Sept. 3, 1918, Halvorsen, B. F. Potash-bearing silicate is heated with CaO, C. and N or with CaC_2 and N, or with $Ca(CN)_2$, to a temperature above 700°C. with the production of a K–N fertilizer which may be treated further to expel the N.

186422, Sept. 3, 1918, Halvorsen, B. F. Potash-bearing silicate is heated with $CaCN_2$ in the presence of superheated steam and the resultant soluble compounds of potassium are recovered.

British patents for processes for extracting potash from silicate rocks.

109105, Sept. 5, 1916, Schmidt, W. A. Mineral silicates, such as feldspar, are roasted in the presence of lime or other alkali earth and preferably also in the presence of sulphur dioxide ond oxygen, whereby the potassium is volatilized and finally condensed and collected.

113211, June 5, 1917, Ashcroft, E. A. Silicates, such as feldspar, leucite, etc., are ground, fused with NaCl or other alkali chloride with the exclusion of air and moisture, and the cooled mass finally lixiviated with water, from which potassium chloride is obtained by evaporation and crystallization.

114743, July 20, 1917, Ashcroft, E. A. Potash feldspar may be treated at a suitable temperature and pressure with lime or magnesia and water or steam with the production of a solution of KOH and a residue suitable for the manufacture of cement.

116118, May 9, 1917, Hone, A. D. Potash-bearing silicate is treated with H_2SO_4 and fluorspar or other fluoride sufficient to liberate HF in such quantity as to remove the Si as tetrafluoride.

116438, Oct. 16, 1917, Dutt, E. E., and Dutt, P. C. Powdered feldspar is heated to a temperature of 700° to 900° C. in a retort into which vapors of $AsCl_3$ are passed. The As_2O_3 distills off, and KCl is obtained by lixiviating the residue and evaporating the solution.

117755, Nov. 5, 1917, Scholes, S. R. Feldspar or other potash mineral is fused with sodium or potassium carbonate, and the ground melt is boiled with water and treated with CO_2 or with cement kiln gases, and the solution is filtered off and evaporated with the production of potassium carbonate.

117870, Nov. 2, 1917, Sschirner, F. Glauconite is heated with lime, sand, chalk, marble, common marl, $CaCO_3$, or corresponding compounds of Mg, Ba, or other alkalies or alkaline earths, and with $CaCl_2$ or NaCl or HCl gas to a temperature of about 800° C. and the product is leached to obtain KCl.

French patent for process for extracting potash from silicate rocks.

483912, August 21, 1917 (see Brit. 103290), Jungner, E. W. The production of alkali carbonate and hydraulic cement from silicates.

Japanese patent for process for extracting potash from silicate rocks.

32516, Apr. 15, 1918, Jungner, E. W. Powdered alkali silicate is heated with lime and coal in the presence of CO_2, flue gas or air to a temperature at which the alkali chloride is driven off.

POTASH FROM KELP.

Kelp yielded 14,029 short tons of potash materials in 1918 containing 4,804 tons of potash (K_2O), which represented 9 per cent of the total domestic output of potash (K_2O). The output was practically all sold and was valued at $2,296,983. About 60 per cent of the product consisted of refined muriate, and nearly all of the remainder consisted of kelp ash and ground kelp. Eight companies, including the Government experiment plant at Summerland, Calif., reported production. Seven of the plants are in southern California and were in operation in 1917; one is in Washington and began operations in the latter part of 1918.

The companies which reported production of potash from kelp during 1918 are as follows:

Hercules Powder Co., Chula Vista, Calif.
Diamond Match Co., Wilmington, Calif.
Sea Products Co., Long Beach, Calif.
Pacific Products Co. of California, Long Beach, Calif.
Swift & Co., San Diego, Calif.
Lorned Manufacturing Co., Summerland, Calif.
United States Department of Agriculture, Summerland, Calif.
Puget Sound Kelp & Fertilizer Co., Seattle, Wash.

The Occidental Chemical Co. (formerly the California Chemical Co.), Summerland, Calif; San Simeon Reduction Co., San Simeon, Calif.; and the Southern Reduction Co., San Diego, Calif., were in operation during 1917, but reported no production in 1918.

Reports indicate that the kelp-potash producers closed their plants early in 1919 and later most of them were dismantled in anticipation of prices at which they could not compete, the governmental plant being the only one that continued in business. Available supplies of easily accessible kelp on the Pacific coast are sufficient to yield probably between 5,000 and 10,000 tons of actual potash (K_2O) annually. The capacity of the kelp-potash plants in 1918 was about 5,000 tons. Revival of the industry apparently will depend on the recovery of

by-products such as iodine, acetone, ammonia, and charcoal by methods that are being investigated by the Department of Agriculture experimental plant at Summerland.

POTASH FROM MOLASSES DISTILLERY WASTE.

Eight companies produced and sold from molasses distillery waste 11,792 tons of potash materials in 1918, containing 3,467 tons of actual potash (K_2O), valued at $1,335,516. The production represented an increase of about 22 per cent in K_2O over that in 1917. The products consisted for the most part of ash and crude potash salts containing from 24 to 38 per cent of K_2O. Small quantities of materials containing less than 20 per cent of K_2O were also marketed.

The following firms, the last three of which made only small experimental production during the first half of the year, reported production in 1918:

Mason By-products Co., San Francisco, Calif.
Western Industries Co., Agnew, Calif.
Mifflin Chemical Corporation, Philadelphia, Pa.
Puerto Rico Distilling Co., Arecibo, P. R.
Jefferson Distilling & Denaturing Co., Harvey, La.
United States Industrial Alcohol Co., New Orleans, La
Northern Alcohol Co., Billings, Mont.
Joslin Schmidt Co., Cincinnati, Ohio.

Estimates place the potash (K_2O) which could be recovered annually in the United States as a by-product in the manufacture of industrial alcohol from molasses at 30,000 tons. More than 80 per cent of this potential supply of potash, now lost, is contiguous in the Eastern States to large centers of the consumption of potash.

POTASH FROM STEFFENS WASTE WATER IN BEET-SUGAR MANUFACTURE.

The recovery of potash from the large quantities of beet molasses now annually reworked for sugar, chiefly by the Steffens process, received considerable attention in 1918. Eight companies reported production from this source during the year 1918, amounting to 8,795 tons of crude materials, containing 1,374 tons of potash (K_2O). This quantity of potash is more than three times that produced in 1917 from this source. The sales amounted to 3,650 tons of crude materials containing 742 tons of potash (K_2O), valued at $267,309. The product consisted of concentrated potash liquors and potash char. Concentrated liquors containing from 7.5 to 11 per cent of potash, obtained by evaporating Steffens waste liquors, were produced by three companies. Potash char, containing from 32 to 42 per cent of potash, obtained by evaporating the waste liquors and charring the residue, was produced by five companies. A small quantity of crude potassium sulphate, containing 35 per cent of potash (K_2O), was also produced. The following companies reported production in 1918:

American Beet Sugar Co., Oxnard, Calif.
Spreckels Sugar Co., San Francisco, Calif.
Great Western Sugar Co., Denver, Colo.

Columbia Sugar Co., Bay City, Mich.
Holland-St. Louis Sugar Co., Decatur, Ind.
Holly Sugar Corporation, Huntington Beach, Calif.
Larrowe Construction Co., Mason City, Iowa.
United Engineering Co., Blissfield, Ind.

The Great Western Sugar Co. constructed a plant during 1918 at Scotts Bluff, Nebr., for recovering potash from Steffens waste waters from the sugar refineries at Scotts Bluff and Gering.

Potash (K_2O) which could be recovered and which is now going to waste in Steffens water from beet-sugar refineries is estimated at 8,000 tons. Steffens waste waters are very dilute and require the evaporation of large volumes of water in order to recover the potash. The cost of production is in consequence rather high. Dry distillation of the residue from Steffens waste liquor with the production of cyanides, ammonia, fuel gases, and other products whereby both the organic and inorganic constituents are conserved, may eventually result from efforts to recover the potash. The problem of saving both the potash and the nitrogen deserves careful consideration.

POTASH FROM WOOD ASHES.

Fifty-one firms reported the production in 1918 of 1,100 short tons of crude potash from wood ashes, estimated to contain 673 tons of pure potash. The production was a slight increase over that for 1917, which was 1,035 tons of crude potash. The sales amounted to 1,063 tons of crude potash, containing 651 tons of potash (K_2O), valued at $549,745. In 1918 the output consisted of 914 tons of crude potassium carbonate containing 533 tons of K_2O, and 186 tons of caustic potash containing 140 tons of K_2O. The following firms reported production from this source during the year:

INDIANA.

Indiana Chemical Co., Ellettsville.

MAINE.

Fairfield Potash Manufacturing Co., 180 Main Street, West Benton.
Maine Potash Co., Keekan.

MICHIGAN.

Anderson Bros., Route 1, Box 150, Traverse City.
Baraga Potash Co., Baraga.
Boyne City Potash Co., Boyne City.
Burley, Wm. C., & Co., Munising.
Campbell, Wm. T., Potash Co., Trout.
East Jordan Potash Co., East Jordan.
Escanaba Potash Co., Escanaba.
Gaylord Potash Co., Gaylord.
Iron Mountain Potash Factory, Iron Mountain.
Isham & Isham, Detroit.
Johnson, Albin, Jennings.
Manistique Potash Co., Manistique.
McClory, James, 115 East Spratt Street, Alpena.
Menominee Potash Co., Menominee.
Monroe Chemical Co., 211 Hammond Building, Detroit.
Peter Bloomquist Co., Cadillac.

Prentice, Orson W., & Son, West Branch.
Riley Potash Factory, St. Johns.
Salling Hanson Co., Grayling.
Schwartz, August, Pellston.
Teachman, G. E., Ithaca.
Thomas, E. A., 400 Wisner Street, Saginaw.
Trapp, R. W., Route 1, Mount Clemens.
Wood, Silas E., Maple Rapids.

OHIO.

Butler, E. W., Napoleon.
Englehart, Phillip, Luckey.

TENNESSEE.

Union Chemical Co., Mallory Branch, P. O., Memphis.

WISCONSIN.

Abbotsford Soap & Potash Co., Abbotsford.
Baldwin Brothers, Oconto.
Cotter Brothers, Park Falls.
Eau Claire Potash Co., Eau Claire.
Erskine Potash Co., Washburn.
Fagon, Henry, Merrill.
Forest County Potash Co., Soperton.
Goodman Lumber Co., Goodman.
Great Northern Manufacturing Co., Antigo.
Heinzkill, John, Appelton.
Ladysmith Potash Co., Ladysmith.
Marinette Potash Co., Marinette.
Mattoon Potash Co., Mattoon.
Medford Potash Co., Medford.
Oshkosh Potash & Chemical Co., Oshkosh.
Phillips Potash Co., Phillips.
Rhinelander Potash Co., Rhinelander.
Wausau Potash Factory, Wausau.
Wausau Soap Co., Wausau.
West Lumber Co., Lugerville.
Wisconsin Potash Co., Shawano.
Wisconsin Potash Co., Tomahawk.

The wood-ash potash industry centers around the hardwood lumber districts of Michigan and Wisconsin. Fresh ashes are required for good results. The districts in Michigan and Wisconsin are thoroughly worked at present, so that production from these States could not be much increased. Conditions in other States with regard to the supply of hardwood ashes are not so well known, but production in many other localities is probably feasible.

Ernest Bateman,[1] of the Forest Products Laboratory, United States Department of Agriculture, Madison, Wis., has made a careful study of the wood-ash potash industry and has estimated that 2,075 tons of K_2O could be produced annually in the United States from easily collectible wood ashes from hardwood sawmills. His figures as related to a number of different States are presented in the following table:

[1] Bateman, Ernest, Wood ashes and production of potash: Met. and Chem. Eng., vol. 20. 1919.

Estimated possible annual production of potash from wood ashes.

State.	Available annual supply of wood ashes (short tons).	Potash (K_2O) (short tons).	State.	Available annual supply of wood ashes (short tons).	Potash (K_2O) (short tons).
West Virginia	6,800	245	North Carolina	2,400	85
Michigan	6,000	215	Indiana	2,200	80
Arkansas	5,100	185	Missouri	2,000	70
Wisconsin	4,700	170	New York	1,900	70
Tennessee	4,300	155	Vermont	800	30
Kentucky	3,900	140	Texas	700	25
Pennsylvania	3,500	125	Maryland	600	20
Virginia	3,200	115	Maine	500	20
Ohio	3,100	110	South Carolina	500	20
Mississippi	3,000	110			
Louisiana	2,400	85		57,600	2,075

This estimate, which includes only ashes from hardwood sawmills, appears to be conservative. For instance, the table indicates a possible annual production from hardwood ashes in Wisconsin at 170 tons of K_2O, whereas the actual production of potash from wood ashes from all sources in Wisconsin in 1918, as reported to the United States Geological Survey, was 398 tons.

Potash-producing plants as used in Wisconsin, according to Bateman, cost between $3,000 and $4,000, and the cost of manufacturing crude potash ranges from about 7 to 17 cents a pound. It may be reduced under certain conditions to 5 cents a pound and enable the output to compete on a small scale with imported potash.

POTASH FROM WOOL WASHINGS AND MISCELLANEOUS SOURCES.

In 1918 four companies were engaged in producing potash from wool washings and miscellaneous sources. The production and sales amounted to 931 tons of materials, containing 289 tons of potash (K_2O), and was valued at $138,688. The product consisted of refined muriate and of ash containing from 12 to 20 per cent of K_2O. The producing companies were the Diamond Match Co., Lawrence, Mass.; Arlington Mills, Lawrence, Mass.; California Potash Co., Sacramento, Calif.; Neo Manufacturing Co., Reno, Nev. The source of the potash produced by the two western firms was largely vegetable ash.

POTASH FROM FOREIGN SOURCES.

GERMANY.

The potash deposits of Germany, which were discovered by the Prussian Government in 1843 at Stassfurt while boring for rock salt and which occur in upper layers of rock salt in the plains of northern Germany, have been estimated to occupy a volume of 10,790,000,000 cubic meters and to contain 20,000,000,000 metric tons of potash salts, corresponding to about 2,000,000,000 metric tons of potash (K_2O), a quantity sufficient to supply the world for 2,000 years at

the present rate of consumption. These beds were first exploited about 1860, and have furnished practically the entire world's supply of potash for many years. The total quantity of raw potassium salts mined in Germany, including Alsace, is shown in the following table:

Raw potassium salts mined in Germany,[a] 1861–1917, in metric tons.

Year.	Number of works.[b]	Carnallite.	Kieserite.	Kainite, including hartsalz and schönite.	Sylvinite.	Total.

Knapp, Halle, Germany, 1919.

Although a large part of the crude salts mined are subjected to manufacturing processes to produce higher grade salts before marketing, most of the kainite and some of the sylvinite and other salts are sold as they come from the mines. The sales of manufactured and crude-potassium salts during selected years since 1880 from the German and Alsatian mines are shown in the following table:

Crude and manufactured potassium salts sold from the German and Alsatian mines,[a] 1880–1918, in metric tons.

Year.	Muriate of potash (80 per cent).	Sulphate of potash (90 per cent).	Sulphate of potash and magnesia (48 per cent).	Sulphate of potash and magnesia (40 per cent).	Manure salts.	Kainite and sylvinite.[b]	Total crude and concentrated salts.	Total K_2O.	Value.[c]

[c] Calculated from original values given in marks, 1 mark being considered equivalent to 23.8 cents.

[d] Not available.

[e] Allotment for 1918.

Prior to the war Germany consumed about one-half of the potash produced by the German and Alsatian mines, the United States about one-fourth, and European countries nearly all the remainder. During the war Germany used a much larger proportion of the output, while the United States, France, England, Italy, and non-European countries used practically none. The following table shows the distribution of sales of potash by countries from the German and Alsatian mines from 1909 to 1917. The figures for the years 1909 to 1913 represent the total sales; those for the years 1914 to 1917 represent sales for fertilizers only. As about 10 per cent of the output is used in chemical industries, the figures for 1914–1917 should be increased by about 10 per cent to make them comparable with the figures for the earlier years.

Potash (K_2O) sold from the German mines, by countries, 1909–1917, in metric tons.[a]

Country.	1909	1910	1911	1912	1913	1914	1915	1916	1917

[a] Figures for 1909–1913 are taken from Federal Trade Commission report on the fertilizer industry, p. 107. Those for 1914–1917 are taken from Wohltmann F., op. cit. p. 32, and include potash for fertilizer use only, and should be increased about 10 per cent to make them comparable with figures for other years.

ALSACE.[1]

Potash salts were discovered at Wittelsheim, 6 miles northwest of Mulhouse, in upper Alsace, in 1904, in drilling for oil. Subsequent explorations and developments indicate that the deposits underlie an area of more than 70 square miles, and that the workable beds have a depth of about 2,000 feet and range in thickness from 6 to 30 feet. The salts consist essentially of sylvinite, a mixture of sylvite and rock salt. Practically no carnallite or magnesium chloride is present. Estimates place the quantity of potash salts in the deposit at 1,472,058,000 metric tons, which on a basis of 22 per cent of potash (K_2O) gives more than 300,000,000 tons of potash (K_2O). The first mining shaft was completed in 1909 and production began in 1910. In 1913 40,707 tons of potash (K_2O) was produced from this source. The German Kali Syndicate, which controlled these mines as well as those at Stassfurt, determined the proportion of potash to be produced by the Alsatian mines at about 4 per cent of the total annual production from Germany. The main object in limiting the output was to prevent overproduction and thus a lowering of the price.

When the armistice was signed in November, 1918, the Alsatian mines were transferred to French control and apparently were in a very bad state of repair. A summary of the preliminary report on

[1] Förster, B., Ergebnisse der Untersuchung von Bohrproben im Tertiär Oberelsass: Geol. Landesanstalt Elsass-Lothringen Mitt., vol. 7, No. 4, 1911. Binder, Félix (and others). Mines de potasse dans la Haute-Alsace: Soc. ind. Mulhouse Bull., vol. 32, No. 4, pp. 207–300, April, 1912. Wehrlin, A. (chairman of commission), Die Kalibergwerke in Oberelsass: Jahresb. der Ind. Ges. von Muelhausen, Stuttgart, 1913. The world's supply of potash, London, Imperial Institute of the United Kingdom, 1915. Kestner, Paul, The Alsace potash deposits: Soc. Chem. Industry Jour., London, Nov. 15, 1918, pp. 291T–299T.

the Alsace potash fields prepared in April, 1919, by H. S. Gale, of the United States Geological Survey, who visited the mines early in 1919, is as follows:

1. Seven mines are in operation.
2. Several other mines are being put into operating condition.
3. Able technical talent has been obtained and excellent progress made in rehabilitating the properties.
4. The mines compare fairly well in size and equipment with the best German mines.
5. The daily production is about 2,300 tons of potash salts, averaging about 20 per cent of potash (K_2O), or 460 tons, corresponding to about 150,000 tons of (K_2O) per year.
6. Stocks on hand amount to 62,500 tons of low-grade salts containing nearly 8,000 tons of actual potash (K_2O).
7. February quotations for domestic consumption, delivered at Rotterdam, were about 60 cents per unit of potash (20 pounds of K_2O).
8. Export prices have not been established.
9. Shipping cost from Mulhouse to Rotterdam is about $2.50 per ton.

SPAIN.

Potash deposits were discovered a few years ago in the Province of Barcelona, Spain, near the villages of Suria and Cardona. The salts occur in Oligocene (Tertiary) formations. They consist of irregular beds of carnallite and sylvinite interbedded with and occurring in rock salt. Explorations to a depth of several hundred feet show that in the Suria district potash beds occupy an area of not less than 75 acres and occur at depths from 125 to 200 feet. The average combined thickness of the carnallite beds is estimated to be about 56 feet, and of the sylvinite about 13 feet. The Cardona deposits occur in the axis of a sharp anticline about 220 yards from Cardona. The upper beds are interbedded with gypsum and clay, but the lower beds contain nearly pure white salt, which is that principally mined. After the discovery of potash at Suria, these Cordona beds were searched for potash, and nearly pure sylvite was found. Estimates for the area prospected place the quantity of carnallite at 2,550,000 tons and of sylvinite at 1,150,000 tons.

No production has been reported from this source, but explorations and development are in progress.

GALICIA.

The potash deposits near Kalusz, Galicia, occur at four different horizons in lenticular beds, which attain a thickness of 20 feet and are interbedded with rock salt and saline clay. They contain kainite and sylvinite with relatively small quantities of carnallite and yield an average of about 10 per cent of potash (K_2O). The explored portion of the uppermost bed is estimated to contain more than 100,000 tons of potash salts. The present production is about 1,000 tons of potash (K_2O) annually, which is not sufficient to supply the Galician demands.

CHILE.

The caliche of the Chilean nitrate fields contains from a trace to more than 17 per cent of potassium nitrate. Probably the average is about 2 or 3 per cent. The Du Pont Nitrate Co.[1] began the pro-

[1] Barton, C. M., Met. and Chem. Eng., vol. 18, p. 248, 1918.

duction of potassium nitrate from the caliche as a by-product in the manufacture of sodium nitrate in 1914 and now has an annual productive capacity of 10,000 tons of a 25 per cent potassium nitrate, representing nearly 1,200 tons of potash (K_2O). The process consists in evaporating the mother liquors from the crystallizing pans to a high density and then cooling the concentrated brine, thus causing a product containing about 25 per cent potassium nitrate to be deposited. The details of this process have been given by the Du Pont Nitrate Co. to other Chilean nitrate producers. The Du Pont Co. produces only about 1 per cent of the total output of the sodium nitrate from the Chilean fields. Potash recovery by all the nitrate-producing companies would result in an estimated annual saving of 120,000 tons of potash (K_2O). Projected improvements in the process may recover practically all the potash from the caliche, which would represent a total estimated output of 320,000 tons of potash (K_2O) for the nitrate industry.

ITALY.

Extensive deposits of alunite occur near Tolfa, Italy, and are utilized in the production of potash salts. Estimates in 1908 placed the ore available at 150,000 to 200,000 metric tons. The quantity[1] of alunite utilized was 3,700 metric tons in 1914 and 4,850 metric tons in 1915.

OTHER COUNTRIES.

So far as known the potash resources of other countries are limited and have yielded only small quantities of potash. They were described in the report for 1917, and the descriptions will not be repeated here, as little or no developments are on record for 1918.

POTASSIUM (METAL).

Metallic potassium (K), a soft white metal, is obtained commercially by electrolyzing fused potassium chloride or potassium hydroxide. It is a powerful reducing agent and has been employed in the preparation of boron, silicon, and various organic compounds and in the analysis of gases. There is, however, no great demand for metallic potassium, as the cheaper sodium is equally applicable for almost all purposes.

No data on domestic production are available, and presumably little or none has been made. Imports in 1914 amounted to 998 pounds, valued at $330, or about 33 cents a pound.

POTASSIUM ACETATE.

Potassium acetate ($KC_2H_3O_2$), which is a deliquescent salt occurring in some vegetable secretions, is obtained commercially by the action of acetic acid on caustic potash or potassium carbonate and also by decomposing lead acetate with potassium carbonate. The commercial salt is liable to contain sulphates, chlorides, carbonates, and heavy metals, and is sometimes intentionally adulterated with

[1] Rivista del Servizio minerario, 1915, p. 182.

calcium acetate or other ingredients. It is used in bleaching and dye works, in medicine, and in preparing tincture of ferric acetate. Five companies produced 93,307 pounds of 98 to 99 per cent potassium acetate in 1918. The sales amounted to 90,229 pounds, valued at $59,314. Domestic production in other years is not known. Data on imports and exports in 1918 are not available. Imports for the fiscal year ending June 30, 1914, were 528 pounds, valued at $108, or about 20 cents a pound.

The following companies reported production of potassium acetate in 1918:

Albany Chemical Co., Albany, N. Y.
Mallinckrodt Chemical Works, St. Louis, Mo.
Powers-Weightman-Rosengarten Co., Philadelphia, Pa.
Smith, Klein & French Co., Philadelphia, Pa.
E. R. Squibb & Sons, New York, N. Y.

POTASSIUM ALUMINUM SULPHATE (POTASH ALUM).

Potash alum, hydrous potassium-aluminum sulphate ($K_2SO_4Al_2(SO_4)_3.24H_2O$), occurs as an efflorescence or incrustation in many parts of the world, particularly in volcanic regions and where pyritic shales and similar materials are undergoing decomposition. It is very soluble in hot water, rather sparingly soluble in cold water, crystallizes well, and is easily prepared in the pure state.

The main uses of potash alum are in dyeing, in the manufacture of lake pigments, in dressing skins, in fireproofing, in sizing paper, in water purification, in the preparation of other aluminum salts, and in medicine. Being more economical, aluminum sulphate and soda alum are gradually replacing it in most of its applications. These materials do not crystallize well, however, and are difficult to prepare pure, whereas many operations, especially in dyeing, require a material free from iron and other impurities. Hence, the superiority of potash over these substitutes.

From time to time small quantities of the natural alum from Italy, Nevada, and other localities have been purified and marketed. Considerable quantities are produced annually from alunite in Italy and Utah. The process employed in Italy consists in roasting the ore at about 500° C., digesting the residue with water or sulphuric acid, and finally crystallizing the alum. A more modern process consists in calcining the alunite at a higher temperature, digesting the residue with sulphuric acid, adding the requisite amount of potassium chloride, and crystallizing the alum. Alum is still manufactured to a small extent, particularly in England, by digesting with water or roasting finely ground pyritic aluminous shale, lixiviating with water, and crystallizing the product. Sulphuric acid and potassium sulphate may be added to increase the yield. The bulk of potash alum, however, is made in normal times by combining in proper proportions solutions of aluminum sulphate and potassium sulphate and crystallizing the product.

Burnt alum, anhydrous potassium-aluminum sulphate ($K_2SO_4.Al_2(SO_4)_3$), is obtained as a porous mass slowly soluble in water by roasting ordinary alum at a temperature above 100° C.

From 1912 until the war began in 1914 market quotations on lump potash alum ranged from about 1¾ to 2 cents a pound. The price

rose to 5 cents a pound in 1915, to 8 cents in 1917, and to 12 cents in October, 1918. The domestic output in 1918 sold for about 2½ cents a pound according to reports submitted to the Geological Survey.

The domestic production in 1918 of potash alum and burnt alum of various grades amounted to 10,922,955 pounds, and the sales were only a little less, amounting to 9,699,645 pounds, valued at $251,181. A summary of the production of potash alum and burnt alum in the United States is shown in the following table:

Potash and burnt alum produced in the United States, 1899–1918.[a]

	1899		1904		1909		1914		1918[b]	
	Quantity (pounds).	Value.	Quantity (pounds).	Value.	Quantity (pounds).	Value.	Quantity (pounds).	Value.	Quantity (pounds).	Value.
Potash alum	14,200,000	$215,004	10,307,000	$156,448	10,254,000	$155,319	12,765,000	$219,968	.....	.....
Burnt alum.	6,629,000	174,600	15,858,000	364,328	11,746,000	209,904	22,629,000	364,656	.....	.....
	20,829,000	389,604	26,165,000	520,776	22,000,000	365,223	35,394,000	584,624	9,699,645	$251,181

[a] Data except for 1918 taken from Census of manufactures, chemicals, and allied industries, 1914, U. S. Dept. Commerce Bur. Census.
[b] Sales.

The annual importation of potash alum is known to be small, although no figures are available except for the fiscal year ending June 30, 1914, when 270,114 pounds, valued at $3,493, came into the country. England furnished a large part of this importation and Belgium the remainder.

Reports of production of potassium aluminum sulphate in 1918 were received from the following companies:

American Smelting & Refining Co., Murray, Utah.
E. I. du Pont de Nemours & Co., Wilmington, Del.
Superior Chemical Co., Joliet, Ill.

POTASSIUM BICARBONATE.

Potassium bicarbonate ($KHCO_3$) crystallizes well and is corparatively easy to purify. The saturated solution loses carbon dioxide on boiling, and the solid salt is completely decomposed at 190° C., with the resulting formation of the normal carbonate. It is used in the manufacture of pure potassium carbonate, as a chemical reagent, and in other ways. It may be prepared in several ways, but it is usually obtained commercially by saturating a strong solution of the normal carbonate with carbon dioxide gas and crystallizing the product.

Market quotations before the war ranged around 5 cents a pound; in 1915 the price was from 30 to 50 cents; in 1916, from 50 cents to $1.46, and in 1917 and 1918, from $1.25 to $1.50.

Only one firm, the Mallinckrodt Chemical Co., St. Louis, Mo., reported production in 1918, and the figures are included with those of potassium carbonate (p. 389). The product was about 99 per cent pure. Import figures for the years 1913 to 1918 are shown on pages 391–392. For the fiscal year ending June 30, 1914, the imports were 478,903 pounds, valued at $22,783, of which 88 per cent came from England and the remainder from Germany and Austria.

POTASSIUM BICHROMATE.

Potassium bichromate ($K_2Cr_2O_7$) is one of the most useful of the chromium salts. It is a powerful oxidizing agent, is stable under ordinary conditions, and finds wide application in chemical industries. Its principal uses are in the manufacture of chrome-yellow and other inorganic pigments and of other chromium compounds, in the manufacture of dyes and other organic compounds, in pyrotechnics, in tanning, in dyeing, in calico printing, in making blue-print paper, in electro-engraving of copper plates, in the autotype and other similar photographic printing processes, in photography, as an oxidizing agent, and as a chemical reagent. In recent years its use has been very largely reduced and its place taken by the cheaper sodium bichromate. Potassium bichromate is prepared by heating to a sintering temperature finely powdered chromite, potassium carbonate, and lime in an oxidizing atmosphere, lixiviating with water, adding potassium sulphate, slightly acidifying with sulphuric acid, and finally crystallizing out the potassium bichromate thus formed. It is also obtained by treating solutions of sodium bichromate with potassium chloride. The salt crystallizes well, making purification easy.

Market quotations of potassium bichromate before the war (1912–1914) were about 7 cents a pound. They rose to 75 cents a pound early in 1916 and then declined, ranging from 39 to 48 cents in 1918.

The figures of production for 1918 have been combined with those of potassium chromate. The total output of these two salts, which were of 98 per cent or higher grade and which consisted chiefly of bichromate, was 681,346 pounds, and the sales, including those of reserve stocks, were 1,003,598 pounds, valued at $407,793. Data for other years are not available, but it is known that for many years domestic producers have largely supplied the consumption. Import figures for 1913 to 1918 are shown on pages 391–392. Imports of bichromate, which came from Austria and Germany, for the fiscal year ending June 30, 1914, were 30,088 pounds, valued at $2,362.

The three firms that reported production of potassium bichromate to the United States Geological Survey for 1918 were as follows:

Michel-Bilodeau Chemical Co. (Inc.), San Francisco, Calif.
Mutual Chemical Co. of America, Jersey City, N. J.
Natural Products Refining Co., Jersey City, N. J.

POTASSIUM BINOXALATE.

(See Potassium oxalate.)

POTASSIUM BISULPHATE.

Potassium bisulphate ($KHSO_4$) occurs native in volcanic regions, notably near Naples, Italy. It is obtained by the action of sulphuric acid on potassium chloride or nitrate and is an intermediate product in the production of potassium carbonate by the Le Blanc process.

The Mallinckrodt Chemical Co. is the only firm that reported production in 1918, and the figures are included with "all others" in the table on page 389. No data are available on production in other years or on imports, except that in 1914 imports valued at less than $100 came into the country.

POTASSIUM BISULPHITE.

(See Potassium sulphites.)

POTASSIUM BITARTRATE.

(See Potassium tartrates.)

POTASSIUM BROMIDE.

Potassium bromide (KBr) is formed along with bromate when bromine is dissolved in caustic potash, and on evaporation and gentle ignition, preferably in the presence of carbon, the bromate is decomposed with the formation of bromide. It is usually prepared, however, on a large scale by decomposing ferrous bromide, obtained by the action of bromine and water on iron filings, with potassium carbonate, and is purified by recrystallization. Impurities which often contaminate the commercial article are potassium chloride, iodide, and carbonate. Potassium bromide serves as a valuable medicine, especially in cases of nervous diseases, and is used extensively for pharmaceutical purposes, in photography, and as a chemical agent.

Market quotations in 1914 before the war were about 40 cents a pound; this advanced to more than $5 a pound early in 1916. They then declined and ranged from $1.25 to $1.46 a pound in 1918. The domestic output in 1918 sold at an average of a little less than 90 cents a pound.

Domestic production in 1918, as reported to the United States Geological Survey, amounted to 666,119 pounds of United States Pharmacopoeia grade, and the sales amounted to 616,232 pounds, valued at $551,079. Data on production for other years, on imports, and on exports are not available, except that for the fiscal year ending June 30, 1914, 361 pounds were imported, valued at $200.

The following three firms reported production of potassium bromide in 1918:

J. Q. Dickinson & Co., Malden, W. Va.
The Dow Chemical Co., Midland, Mich.
The Heyden Chemical Works, Garfield, N. J.

POTASSIUM CARBONATE.

Potassium carbonate (K_2CO_3) is extremely hygroscopic, is very soluble in water, and crystallizes with difficulty. It possesses a strong alkaline reaction and a caustic taste.

Potassium carbonate is used largely in the manufacture of Bohemian and flint glass, soft soap, potassium hydroxide, acetate, iodide, bromide, bichromate, permanganate, ferrocyanide, silicate, in wool washing, and in bleach and dye works.

It was originally produced solely by lixiviating the ashes of wood and plants and evaporating the lye thus obtained in pots—hence the name potash. Considerable quantities were produced in America and Russia from this source during the European war, the Russian product coming principally from sunflower ash. The crude product, known as crude first sorts, contains a considerable proportion of sulphate and other impurities, and if lime is used in the

process caustic potash will replace more or less of the carbonate. It is often partly refined to produce a salt containing about 90 per cent of potassium carbonate. One method of refining is by calcining with sawdust, lixiviating with water, allowing the solution to stand in order to separate sulphate and other impurities, and evaporating the clear solution to produce a white salt known as pearl ash.

Although potassium carbonate may be prepared in many ways the bulk of it in normal times is manufactured either by the magnesia-potash process or the Le Blanc process. The magnesia-potash process, which is used extensively in Germany and which has largely replaced other methods, depends on the decomposition of potassium chloride by carbon dioxide in a suspension of magnesium carbonate below 24° C. with the formation of the sparingly soluble compound $KHCO_3.MgCO_3.4H_2O$, which is in turn transformed into potassium carbonate and magnesium carbonate by treatment with hot water or magnesium hydroxide. In the Le Blanc process, which is used largely in the manufacture of soda ash, potassium sulphate, coal, and limestone are calcined to produce a product technically known as "black ash," which contains potassium carbonate, calcium sulphide, unburned coal, unaltered potassium sulphate, etc. On lixiviating the "black ash" potassium carbonate goes into solution along with the various impurities. As potassium carbonate is exceedingly soluble much of the potassium sulphate, ferrocyanide, and other impurities are removed by allowing the concentrated solution to stand. The product finally evaporated contains from 80 to 90 per cent of K_2CO_3 and is frequently refined by re-solution, evaporation and calcining to a product containing from 92 to 98 per cent of K_2CO_3.

A very pure hydrated potassium carbonate free from sulphates and containing 12 to 18 per cent of water is manufactured for certain purposes, particularly for making optical glass. One method is to dissolve ordinary carbonate in water and allow the concentrated liquor to cool and settle, which causes nearly all the sulphate and other impurities to separate. The clear liquor is then evaporated in flat pans to a thick paste, the fire is drawn, and the mass is stirred until it is converted into a coarse powder. The composition of the product approaches the formula $K_2CO_3.2H_2O$.

Chemically pure potassium carbonate, which was formerly obtained by igniting pure potassium bitartrate, is now prepared by calcining pure potassium bicarbonate.

Market quotations from 1912 to 1914, before the war, on 80 to 85 per cent calcined carbonate ranged from 3 to 4 cents a pound. The price advanced to about 90 cents in 1916 and then declined, ranging from 30 to 60 cents a pound in 1918. Quotations on 80 to 85 per cent hydrated potassium carbonate ranged around $3\frac{3}{4}$ to $4\frac{1}{2}$ cents a pound from 1912 to 1914, advanced to $1.15 a pound in 1916, and varied from about 80 cents to $1.25 in 1918. At the same time quotations on 96 to 98 per cent calcined potassium carbonate ranged from $4\frac{1}{4}$ to $4\frac{3}{4}$ cents a pound from 1912 to 1914, advanced to $1.10 in 1916, and ranged from 50 to 80 cents in 1918. The average selling price of the domestic output of crude carbonate from wood ashes in 1918 was a little less than 19 cents a pound and the selling price of the domestic output of refined hydrated carbonate ranged from 40 to 75 cents a pound.

In 1914 the domestic output of unrefined and refined carbonate was valued at $19,007.

The total domestic output of crude carbonate from wood ashes in 1918 was 1,827,000 pounds, compared with a production in 1914 valued at $30,644. A list of producers is shown on pages 413–414.

The production of refined carbonate in 1918 was reported by three companies, and the figures have been combined with those of bicarbonate, as shown in the table on page 389. The combined output of the two salts amounted to 229,287 pounds. The refined product was hydrated and was about 99 per cent pure.

The three producers of refined carbonate in 1918 were:

Armour Fertilizer Co., Chicago, Ill.
Powers-Weightman-Rosengarten Co., Philadelphia, Pa.
Western Alkali Refining Co., Omaha, Nebr.

Imports of crude carbonate were almost as large in 1918 as in 1914, amounting to 8,594,000 pounds, valued at $2,273,202. They were much less in 1915 and 1917, and they amounted to only 682,000 pounds in 1916. At the same time only 208,000 pounds of refined carbonate, valued at $65,974, came into the United States in 1918, compared with 6,742,000 pounds, valued at $224,384, in 1914. Figures of imports for the years 1913 to 1918 are shown on pages 391–392, and more detailed figures for 1914 on page 396.

Exports of potassium carbonate in 1914 were valued at $1,934. No data for exports are available for other years.

POTASSIUM CHLORATE.

Potassium chlorate ($KClO_3$) is an anhydrous nonhygroscopic salt, which is stable at ordinary temperatures. It is a powerful oxidizing agent and finds wide application in chemical industries. Its more important uses are in matches, primers, percussion caps, detonators, blasting powder, pyrotechnics, magnesium flash-light powders, calico printing and dyeing, welding, paints, pharmaceutical preparations, tooth paste, medicine, the manufacture of dyes and other organic compounds, making oxygen in chemical laboratories, and as an oxidizing and chemical reagent. Formerly potassium chlorate was prepared commercially by passing chlorine gas into milk of lime and converting the calcium chlorate thus formed into the potassium salt by treatment with potassium chloride. The modern method consists in electrolyzing a strong solution of potassium chloride at about 50° C. in such a way that the chlorine and potassium hydroxide formed are brought into contact and allowed to react and in crystallizing the potassium chlorate which is formed.

Market quotations ranged from 7 to 10 cents a pound before the war in 1914, advanced to 50 cents in 1915, reached 75 cents in 1916, ranged from 75 to 40 cents in 1917, and from 45 to 28 cents in 1918. The unusual demand for potassium chlorate and the keen competition for the limited supply of potassium chloride used in its manufacture were leading factors affecting the price.

Domestic production and sales in 1918, as reported to the United States Geological Survey, amounted to 9,753,424 pounds, valued at $2,837,892, or about 29 cents a pound. The product was practically

pure, containing from 99.8 to 100 per cent $KClO_3$. Data for other years are not available.

During 1918, 710,000 pounds, valued at $248,160, were imported and 1,392,000 pounds, valued at $534,491, were exported. Data for 1914 show 26,000 pounds of imports, valued at $2,235, and do not show exports. Imports have been very irregular, amounting to more than 1,000,000 pounds in 1913 and 1918 and to only 10,000 pounds in 1916. The available data on imports and exports are summarized on pages 390–397.

Firms reporting production of potassium chlorate in 1918 were:

National Electrolytic Co., Niagara Falls, N. Y.
North American Chemical Co., Bay City, Mich.
Ohio Salt Co., Rittman, Ohio.

POTASSIUM CHLORIDE.

Potassium chloride (KCl) is produced in large quantities in Germany and Alsace from carnallite and sylvinite, and during the war considerable quantities were produced in the United States from brine, kelp, cement dust, silicate rock, and wool washings. It is one of the principal fertilizer salts as well as a raw material in the production of many other potassium compounds, notably potassium bromide, bromate, carbonate, chlorate, hydroxide, iodide, iodate, nitrate, and perchlorate. According to the Federal Trade Commission,[1] nearly 10 per cent of the potassium chloride imported before the war was used for chemical purposes. Little information is at hand to show the proportion of the domestic output used in fertilizers and in chemical industries, but it is believed that most of the high-grade product was used in chemical industries.

The total domestic output in 1918 of grades containing 60 per cent or more of KCl was 62,972,000 pounds, containing 41,741,300 pounds of pure KCl. Of this quantity 9,458,000 pounds contained from 92 to 98 per cent of KCl, 4,238,000 pounds contained from 76 to 80 per cent of KCl, and 49,276,000 pounds contained from 60 to 71 per cent of KCl. Statistics of imports are presented in the tables on pages 391, 393, and 396, exports are shown on page 397, and prices are discussed on pages 397–399.

The following firms reported production in 1918:

American Trona Corp., Trona, Calif.
Atlantic Potash Co., Stockertown, Pa.
Calco Chemical Co., 136 Liberty Street, New York, N. Y.
Coplay Portland Cement Co., Coplay, Pa.
Diamond Match Co., 111 Broadway, New York, N. Y.
Hercules Powder Co., Wilmington, Del.
Ogden Portland Cement Co., Ogden, Utah.
Oliver Chemical Co., Mount Eden, Calif.
Salt Lake Chemical Co., Salt Lake, Utah.
Solvay Process Co., Syracuse, N. Y.

POTASSIUM CHROMATE.

Potassium chromate (K_2CrO_4) is prepared by adding the requisite proportion of potassium carbonate or hydroxide to a solution of potassium bichromate. On evaporation potassium chromate is ob-

[1] Report on the fertilizer industry, p. 115, 1916.

tained in beautiful yellow crystals. It is used largely in the tanning industry. The price in 1918 was between 50 and 60 cents a pound.

Figures of production and importation are combined with those of potassium bichromate, as shown on pages 389, 391, 392, and no data on exports are available. Only one firm, the Mallinckrodt Chemical Co., St. Louis, Mo., reported production of this commodity in 1918, the product consisting of 98 per cent K_2CrO_4.

POTASSIUM CHROMIUM SULPHATE.

Potassium chromium sulphate, chrome alum ($K_2SO_4Cr_2(SO_4)_3$-$.24H_2O$), is obtained by passing sulphur dioxide through a solution of potassium bichromate to which the requisite quantity of sulphuric acid has been added. It is now obtained commercially in large quantity as a by-product in the manufacture of alizarin from anthracene. It is used in dyeing, calico printing, and tanning.

Market quotations in 1917 and 1918 were 20 to 23 cents a pound.

No production of chrome alum in the United States has been reported and no data on imports are available, except for the fiscal year ending June 30, 1914, when 842,200 pounds came into the country, valued at $31,384, or about 3.7 cents a pound.

POTASSIUM CITRATE.

Potassium citrate ($K_3C_6H_5O_7.H_2O$) may be prepared by adding an equivalent quantity of potassium carbonate to a solution of citric acid and evaporating the solution to dryness. It is used extensively in medicine and is an efficient refrigerant, diaphoretic, and diuretic in acute febrile attacks.

Market quotations ranged around 70 cents a pound during the latter part of 1914 and during 1915, advanced to $1.70 a pound early in 1916, and fluctuated around $1.60 to $1.70 a pound during 1918.

Domestic production in 1918 as reported by six firms consisted of 98 per cent or higher grades and amounted to 99,193 pounds; the sales were 96,273 pounds, valued at $141,517, or about $1.47 a pound. Statistics for other years and for imports and exports are not available, except that in 1914 imports were valued at less than $100.

The producing firms in 1918 were:

Albany Chemical Co., Albany, N. Y.
Mallinckrodt Chemical Works, St. Louis, Mo.
Chas. Pfizer & Co., New York, N. Y.
Powers-Weightman-Rosengarten Co., Philadelphia, Pa.
E. R. Squibb & Sons, New York, N. Y.

POTASSIUM CYANIDE.

Potassium cyanide is a white crystalline solid, is very soluble in water, and is a deadly poison. Much of the commercial "potassium cyanide" is actually sodium cyanide. Although sodium cyanide has gradually replaced potassium cyanide in the cyanide process of extracting gold and most of its other applications, potassium cyanide still finds applications in electroplating, photography, casehardening

of iron, the preparation of certain organic compounds, and as an insecticide, especially in fumigating citrous fruit.

Potassium cyanide (KCN) may be obtained in many ways, including the older commercial methods of heating potassium ferrocyanide alone or with potassium carbonate, and the synthetic methods of passing ammonia and potassium vapors over heated carbon, or of fusing calcium cyanamid with potassium carbonate or potassium chloride and carbon. These methods are applicable to the preparation of sodium and potassium cyanides alike.

Market quotations ranged around 20 to 24 cents a pound in 1914, before the war, advanced to $1.20 a pound in 1916, reached $2.50 a pound in 1917, and fluctuated around 60 to 70 cents a pound in 1918. No domestic production was reported for 1918, and figures for other years are not available.

Imports amounted to 24,000 pounds, valued at $10,278, in 1918, compared with 418,000 pounds, valued at $59,278, in 1914. They amounted to 2,649,040 pounds, valued at $394,141, in 1911; to 726,659 pounds, valued at $109,434, in 1912; and to 1,470,987 pounds, valued at $216,844, in 1913. Data for 1914 to 1918 are shown on pages 391–392. Prior to the war imports came principally from Germany; in 1918 they came largely from Spain and Japan.

POTASSIUM FERRICYANIDE.

Potassium ferricyanide ($K_3Fe(CN)_6$), commonly known as red prussiate of potash, is made by passing chlorine gas into a strong solution of potassium ferrocyanide. It is used largely in making blue-print paper and finds some application in photography, in calico printing, and in the production of pigments.

Market quotations ranged from 26 to 33 cents a pound during 1912 and 1913, advanced from 21 to 55 cents a pound in 1914, fluctuated widely in the early part of the war, reached $5 a pound in January, 1916, and ranged from $2.60 to $2.90 a pound during 1918. The average selling price of the domestic output in 1918, which was practically pure, was $1.90 a pound.

Production in 1918 was reported by two firms—Alexander C. Ferguson and Smith, Klein & French, both of Philadelphia, Pa.—and the figures are included under "all others" in the table on page 389 in order not to disclose confidential data. Imports amounted to about 16,000 pounds in 1918, valued at $29,201, and 80,000 pounds in 1914, valued at $14,446, or about 18 cents a pound. Data of imports for 1913 to 1918 are shown on pages 391–392.

POTASSIUM FERROCYANIDE.

Potassium ferrocyanide ($K_4Fe(CN)_6.3H_2O$), commonly known as yellow prussiate of potash, is a yellow crystalline solid, readily soluble in water. On heating it gives off water of crystallization and falls to a white powder. Its main uses are in the manufacture of prussian and other commercial blues, ferricyanide and other cyanogen compounds, in calico printing, in dyeing, and in case-hardening iron. It was formerly obtained by fusing together crude potash, iron filings, and nitrogenous organic matter such as waste

leather or hides, digesting the melt with hot water, and finally crystallizing the ferrocyanide from the solution. It may also be similarly obtained from potassium sulphocyanide and iron filings, and as a by-product in the manufacture of potassium carbonate by the Le Blanc process. It is now produced, however, largely from the spent iron oxide obtained during the purification of coal gas. The spent oxide, which has absorbed the cyanogen compounds along with other substances from the coal gas, is washed with water and carbon bisulphide to remove soluble salts and sulphur. It is then mixed with lime and digested with hot water, when calcium ferrocyanide goes into solution. This is treated with a strong solution of potassium chloride, which precipitates a sparingly soluble potassium-calcium ferrocyanide, and this is finally decomposed with potassium carbonate with the resulting production of potassium ferrocyanide.

Market quotations in 1914, before the war, were about 13 cents a pound, and in 1918 they ranged from 80 cents to $1.30 a pound. According to reports of producers the domestic output in 1918 sold at an average price of about 67 cents a pound.

Domestic production in 1918 consisted of 99 per cent or better grades and amounted to 457,267 pounds, and the sales were 306,535 pounds, valued at $204,190. The production in 1914 was 3,204,684 pounds, valued at $451,092, and in 1909 it was 3,510,208 pounds, valued at $463,983.

Imports in 1918 amounted to 129,441 pounds, valued at $112,729, compared with 3,044,000 pounds in 1914, valued at $334,592. About one-half the imports in 1914 came from Germany, one-fourth from England, and the remainder from France, Austria, Holland, and Belgium. Other data on imports are shown on pages 391, 392, 396. The quantity of exports are not known.

The producing firms in 1918 were:

Bahlman-Frederich Chemical Co., Cincinnati, Ohio.
Calco Chemical Co., New York, N. Y.
Penman-Littlehales Chemical Co., Syracuse, N. Y.

POTASSIUM HYDROXIDE.

Potassium hydroxide, or caustic potash (KOH), although not a potassium salt, is an important commercial potassium compound and is included here for convenience. It is a white deliquescent solid, very soluble in water, and absorbs carbon dioxide from the air. It is one of the strongest bases known.

The principal use of caustic potash is in the manufacture of soft soap, shaving soap, toilet preparations, laundry preparations, pharmaceutical preparations, potassium chromate, and many other potassium compounds, oxalic acid, indigo and other dyes and organic compounds, disinfectants, greases and lubricants, in wool scouring, and as a reagent in chemical laboratories. By far the largest part of it, probably 80 per cent, is used in soft soaps.

Potassium hydroxide is obtained by treating dilute solutions of potassium carbonate with lime at the boiling temperature. Calcium carbonate settles out and the resulting lye is purified by evaporation and filtration until finally fused KOH is obtained. The modern method of preparing caustic potash, which has largely supplanted

other methods, consists in the electrolysis of solutions of potassium chloride.

Market quotations on the 90 per cent grade in 1914, before the war, ranged from 4 to 6 cents a pound, in 1916 from 62 cents to $1 a pound, and in 1918 from 67 to 85 cents a pound. The actual selling price of the best grades produced in 1918 ranged around 70 cents a pound, the average selling price having been a little more than 60 cents for all grades above 88 per cent and about 48 cents for 70 to 80 per cent grades.

Domestic production in 1918, as reported to the United States Geological Survey, amounted to 1,984,847 pounds, and consisted of 1,108,438 pounds, containing 88 per cent or more of KOH, 671,245 pounds containing 70 to 80 per cent of KOH, and 205,164 pounds of solution containing 20 to 45 per cent of KOH. Nearly all the higher-grade product was reported as containing from 88 to 92 per cent of KOH, and nearly all the lower-grade product as a solution containing 45 per cent of KOH. The data of production for 1918, including sales, are shown on page 389, and are not available for other years.

No imports in 1918 were reported. If exports, for which there are no available data, are neglected the available supply of caustic potash in 1918 was 1,984,847 pounds. In 1914, 7,284,000 pounds were imported; unfortunately domestic production and export figures for that year are not available. If exports are neglected, the figures show a far greater supply of caustic potash in 1914 than in 1918. Available data on imports are shown on pages 391, 392, 396.

The following 14 firms reported production of caustic potash in 1918:

Abbotsford Soap & Potash Co., Abbotsford, Wis.
C. F. Burgess Laboratories, Madison, Wis.
Eastern Potash Corporation, Jones Point, N. Y.
Alex. C. Ferguson, Philadelphia, Pa.
Great Northern Manufacturing Co., Antigo, Wis.
John Heinzkill, Appleton, Wis.
Isco Chemical Co. (Inc.), Niagara Falls, N. Y.
Michel-Bilodeau Chemical Co. (Inc.), San Francisco, Calif.
Niagara Alkali Co., Niagara Falls, N. Y.
Oshkosh Potash & Chemical Co., Oshkosh, Wis.
Semet-Solvay Co., Syracuse, N. Y.
August Swartz, Pellston, Mich.
Western Alkali Refining Co., Omaha, Nebr.
Wisconsin Potash Co., Shawano, Wis.

POTASSIUM HYPOPHOSPHITE.

Potassium hypophosphite (KH_2PO_2) may be prepared by boiling phosphorus with a solution of potassium hydroxide and also by decomposing calcium hypophosphite with potassium carbonate. It is used in medicine. No domestic production has been reported to the United States Geological Survey, but in 1914, 300 pounds, valued at $130 was imported.

POTASSIUM IODATE.

Potassium iodate (KIO_3) may be obtained by oxidizing potassium iodide by the electric current or in other ways, but is most readily prepared by heating potassium chlorate with iodine. It is used in medicine and as a chemical reagent.

The Mallinckrodt Chemical Co., St. Louis, Mo., is the only firm that reported a production in 1918, and the figures are combined with those of bromate and perchlorate as shown in the table on page 389. The price was about $3 a pound. During the fiscal year ending June 30, 1914, 62 pounds was imported, valued at $153, or about $2.45 a pound. Statistics for other years are not available.

POTASSIUM IODIDE.

Potassium iodide (KI) is a manufactured product obtained usually by the action of caustic potash on iodine or of potassium carbonate on ferrous iodide. It finds extensive application in medicine, particularly in the treatment of scrofulous and syphilitic diseases, in photography, and as a reagent in chemical laboratories.

In 1918 eight companies produced 521,678 pounds of potassium iodide and sold 481,301 pounds for $1,587,656, corresponding to $3.30 a pound. Imports amounted to 64,000 pounds, valued at $142,324. Exports are not known. Production and export figures for 1914 are not available, and imports amounted to only 270 pounds, valued at $491. These data are too incomplete to give an idea of the relative consumption of potassium iodide in 1914 and 1918. Price quotations ranged from $2.95 to $3.25 a pound in 1914, and from $3.75 to $4 in 1918.

The following companies reported production in 1918:

Albany Chemical Co., Albany, N. Y.
McKesson & Robbins, New York, N. Y.
Mallinckrodt Chemical Co., St. Louis, Mo.
Merck & Co., Rahway, N. J.
Charles Pfizer & Co., New York, N. Y.
Powers-Weightman-Rosengarten Co., Philadelphia, Pa.
Smith, Klein & French Co., Philadelphia, Pa.
E. R. Squibb & Sons, New York, N. Y.

POTASSIUM NITRATE.

Potassium nitrate (KNO_3), better known as saltpeter, is a white crystalline nonhygroscopic solid without water of crystallization. It is much more soluble in hot than in cold water, making purification easy. Its principal uses are in the manufacture of black powder and pyrotechnics, as an oxidizing agent in certain metallurgic and other operations, as a preservative of meats, as a fertilizer, as a chemical reagent, and in medicine to regulate circulation. Black powder is a mixture of potassium nitrate, sulphur, and charcoal, and is used extensively in blasting operations, in base charges for shrapnel shells, in blank-fire charges, in mixtures for small-arms ammunition, in primers and fuses, and as a detonator for smokeless powder charges.[1] Unfortunately the hygroscopic nature of the more economical sodium nitrate precludes its use generally in explosives.

Potassium nitrate is formed in nature through the action of nitrifying bacteria where nitrogenous organic matter is decomposing in the presence of potash. It occurs in many places throughout the world, notably in caves, around native villages in India, Central America, Mexico, and other warm countries, in arid regions in the

[1] See p. 400 for a fuller description of the military uses of black powder.

United States and elsewhere, and forms several per cent of the caliche of the Chilean nitrate fields. During the Civil War considerable quantities were produced from nitrate earths obtained from caves in the Southern States. A considerable portion of the world's supply still comes from nitrate earths in India and Central America. It should be noted, however, that all known deposits of natural potassium nitrate are very small in extent and represent merely impregnations or incrustations of surface materials. In recent years many specimens of potassium nitrate have come to the United States Geological Survey from such deposits in the United States.

Originally all the potassium nitrate of commerce was obtained from nitrate earths, and the industry is still carried on by natives in India, Central America, and some other countries. In the process, which is very crude and which is carried out by each worker on a very small scale, nitrate earth is scraped up in the vicinity of the works and lixiviated in crude vats or pots, and the lye is finally evaporated. The potassium nitrate crystallizes out and is purified by recrystallization. A more rational procedure of mixing wood ashes with the nitrate earth is sometimes followed. The product shipped contains from 70 to 90 per cent of potassium nitrate. More progressive natives in India form nitrate beds of ashes and refuse organic matter and thus increase their supply of nitrate earth and their yield of potassium nitrate.

In recent years, however, the bulk of potassium nitrate in commerce has been produced from sodium nitrate and potassium chloride. The salts are dissolved in hot water or in a mother liquor from a previous operation, brought together in the proper proportion, and concentrated by evaporation until a large portion of the sodium has separated as sodium chloride. On filtering the solution and allowing it to cool, a large part of the potassium crystallizes out as potassium nitrate. The potassium nitrate is purified by washing or by recrystallization.

In 1914, before the war, market quotations on potassium nitrate were about 5 cents a pound, and in 1918 they were 31 cents. The maximum price recorded during the war was 38 cents.

In 1918 the domestic production of potassium nitrate was 16,250,433 pounds, and the sales were 8,176,382 pounds, valued at $2,206,788. The output was all manufactured from potassium chloride and imported sodium nitrate, except 640,000 pounds obtained by refining crude imported saltpeter, there being no commercial deposits of potassium nitrate in the United States. The product was practically pure, containing more than 99 per cent of KNO_3. In 1914 the domestic production amounted to 29,480,000 pounds, valued at $1,244,051. Statistics for other years are not available.

Imports of potassium nitrate are less than domestic production. In 1918 there were imported 9,344,000 pounds of crude nitrate, valued at $906,549, and 4,000 pounds of refined nitrate, valued at $730, which compares favorably in quantity with imports in 1913, 1916, and 1917; in 1914 imports were much less and in 1915 they were practically negligible. The statistics are summarized on pages 391–392. Practically all the crude material came from India, except during 1917 and 1918, when much of it came from South America. Prior to

the war nearly two-thirds of the refined nitrate came from Germany and one-third from England; in 1918 practically all the refined nitrate came from England. Data on exports are not available, except for 1914, when they were valued at $23,286, which probably represented less than half a million pounds of potassium nitrate.

The firms which reported production in 1918 were:

Battelle & Renwick, Jersey City, N. J.
Calco Chemical Co., New York, N. Y.
E. I. du Pont de Nemours & Co., Wilmington, Del.
Hercules Powder Co., Wilmington, Del.

POTASSIUM NITRITE.

Potassium nitrite (KNO_2) is formed by heating potassium nitrate with lead or other metals, with caustic potash and a sulphite, and in other ways. It is also obtained industrially by passing sulphur dioxide into a solution of potassium nitrate containing a suspension of lime. It is used in the preparation of azo-dyes and other organic compounds and as a reagent in chemical laboratories. Before the war it sold for about 20 to 30 cents a pound. No production has been reported in the United States and no data are available on imports, except for 1914, when 414 pounds, valued at $124, came into the United States.

POTASSIUM OXALATES.

Potassium oxalate ($K_2C_2O_4.2H_2O$), which was formerly obtained by heating sawdust with potassium carbonate or hydroxide, is now prepared industrially by heating potassium formate obtained by the action of carbon monoxide on caustic potash. It is used in photography, dyeing, and the preparation of other potassium oxalates. Before the war market quotations were 9 to 10 cents a pound, and the domestic output in 1918 sold for about 67 cents a pound. The Mallinckrodt Chemical Co. is the only firm that reported production in 1918, and the figures are included with "all others," on page 389. The product was about 98 per cent pure. Imports in 1914 amounted to 107,349 pounds, valued at $9,172, or about 8.6 cents a pound.

Potassium binoxalate ($KHC_2O_4.2H_2O$), which occurs in nature in rhubarb, sorrel, and other plants, is formed when normal potassium oxalate is treated with half its equivalent of oxalic or other acid, and is obtained commercially as a by-product in the manufacture of oxalic acid from potassium oxalate. It is used in removing ink stains, in scouring metals, in cleansing wood, and in dyeing. Prices before the war ranged round 9 cents a pound. No domestic production has been reported to the United States Geological Survey, although it is believed that one or two firms produced the salt in 1918. Imports in 1914 amounted to 55,732 pounds, valued at $4,033, or about 7.2 cents a pound.

Potassium titanium oxalate is used as a mordant and is manufactured in the United States by the Eastern Chemical Co., Boston, Mass. In 1914, 77,238 pounds was imported, valued at $10,146, or about 13 cents a pound.

POTASSIUM PERCHLORATE.

Potassium perchlorate ($KClO_4$) may be produced by heating potassium chlorate, when a mixture of the perchlorate and chloride is formed which can be separated by fractional crystallization. A more modern process is by the electrolytic oxidation of potassium chlorate in neutral or acid solution, or, better still, the transformation of the sodium salt thus formed by addition of potassium chloride. The perchlorate has a larger oxidizing capacity than the chlorate, but is more stable. It is used in explosives and in pyrotechnics. Before the war it sold for 9 to 10 cents a pound and in 1918 for 40 to 50 cents.

The Oldbury Electro-Chemical Co., 19 Cedar Street, New York, N. Y., was the only firm that reported production in 1918, and the figures are included with those of bromate and iodate, on page 389. The product contained 99.6 per cent of $KClO_4$. Imports for the fiscal year ending June 30, 1914, amounted to 24,455 pounds, valued at $1,943, or about 8 cents a pound. No other data on production and imports are available.

POTASSIUM PERMANGANATE.

Potassium permanganate ($KMnO_4$) is a powerful oxidizing agent and disinfectant. It finds extensive use in the arts, particularly in the manufacture of saccharine, in bleaching, in dyeing shoe leather, for coloring wood a deep brown, in pharmaceutical and medicinal preparations, in the purification of ammonia and carbon dioxide, as a disinfecting agent, and as an oxidizing and chemical reagent. It is obtained when a solution of potassium manganate is treated with chlorine, ozone, carbon dioxide, or any acid. The modern method of preparing it is to effect the oxidation by means of the electric current. Potassium manganate is obtained by fusing pyrolusite (MnO_2) with caustic potash or potassium carbonate, or by decomposing sodium manganate with potassium chloride.

Market quotations early in 1914 were about 10 cents a pound, and in 1918 they ranged from $4 in January to $1.30 in December and were affected by a shortage in both potash and manganese.

Nine companies reported the production of 562,416 pounds of potassium permanganate of 97 per cent or better grade in 1918, and the sales at 530,837 pounds, valued at $922,746, or about $1.74 a pound. Imports amounted to 54,000 pounds, valued at $128,438, or $2.37 a pound. The quantity of exports is not known. Statistics for other years are not available, except on imports, which are shown in the table on pages 391, 392, 396. Prior to the war the imports came from Germany almost exclusively; in 1918 they came principally from Japan.

The producing companies in 1918 were:

Armour Fertilizer Works, Chicago, Ill.
Carus Chemical Co., La Salle, Ill.
General Supply Co., Perth Amboy, N. J.
Michel-Bilodeau Chemical Co. (Inc.), San Francisco, Calif.
Niagara Alkali Co., Niagara Falls, N. Y.
Pacific Minerals & Chemical Co., Los Angeles, Calif.
Poindexter & Co., Los Angeles, Calif.
Scott & Gilbert Co., San Francisco, Calif.
Secaw Chemical Co., Irvington, N. J.

POTASSIUM PERSULPHATE.

Potassium persulphate ($K_2S_2O_8$) is obtained by the electrolysis of a saturated solution of potassium bisulphate. It is a powerful oxidizing agent and finds a slight application as such, particularly in photography. In 1914 236 pounds was imported, valued at $920, and in 1918 no domestic production was reported. Statistics for other years are not available.

POTASSIUM PHOSPHATES.

Tribasic potassium phosphate (K_3PO_4) may be prepared by heating a mixture of phosphate rock, coke, and potassium sulphate, lixiviating the residue with water, and evaporating the solution. Dibasic potassium phosphate (K_2HPO_4), the most common phosphate of potassium, is obtained by the action of sulphuric acid and potassium bisulphate on calcium phosphate, or by the action of phosphoric acid on potassium carbonate. Monobasic potassium phosphate (KH_2PO_4), obtained by the action of phosphoric acid on potassium carbonate, is also known. These salts crystallize poorly and have little commercial importance, the corresponding soduim salts being usually preferred.

Both the dibasic and the monobasic salts were produced in the United States in 1918, but as only two firms made reports the figures have been included under "all others" in the table on page 389. The products were about 97 per cent pure. The only available data on imports are those for 1914, which are shown on page 396.

Potassium glycerophosphate ($C_3H_7O_3.PO_3K_2$) is formed by neutralizing glycerophosphoric acid with potassium hydroxide or carbonate or by decomposing the calcium salt with potassium carbonate. It is used in medicine. No production has been reported in the United States, and the imports for the fiscal year ending June 30, 1914, amounted to only 244 pounds, valued at $228.

POTASSIUM SILICATE.

Potassium silicate is formed by dissolving silicic acid in a solution of potassium hydroxide or by fusing silica with potassium carbonate and is obtained commercially by melting together quartz sand, potassium carbonate, and powdered coal, and dissolving the residue in superheated water. It is used in cotton printing, fresco printing, in soap, for fixing colors in stereochrome work, in fireproofing, and in making varnishes, etc., but sodium silicate answers equally well for most purposes. The composition of potassium silicate varies, but usually corresponds approximately to $K_2O.4SiO_2$. No production was reported in the United States in 1918. Other statistics are not available except on imports in 1914, when more than 150,000 pounds of solution came into the country, as shown on page 396.

POTASSIUM SULPHATE.

Potassium sulphate (K_2SO_4) is used largely as a fertilizer, particularly in growing tobacco and citrus fruits, and is also used in the preparation of alum and potassium carbonate, and in medicine. It is manufactured on a large scale in Germany from kainite, and

also from potassium chloride by treatment with sulphuric acid. Considerable quantities have been produced during the war from alunite in Utah, and small quantities have been produced from other sources. Prices are discussed on pages 397–399. Statistics of production are shown on page 388, and imports on pages 391–392. According to the Federal Trade Commission,[1] about 2 per cent of the potassium sulphate imported before the war was for chemical purposes, 430 metric tons, or 948,000 pounds, having been imported in 1914 for chemical use.

The following companies reported production of potassium sulphate in 1918:

Mineral Products Corp., Marysvale, Utah.
California Portland Cement Co., Colton, Calif.
Newaygo Portland Cement Co., Newaygo, Mich.
Riverside Portland Cement Co., Riverside, Calif.
Santa Cruz Portland Cement Co., Davenport, Calif.
Southwestern Portland Cement Co., Victorville, Calif.
Portland Cement Co. of Utah, Salt Lake City, Utah.
Tennessee Coal, Iron & Railroad Co., Birmingham, Ala.

POTASSIUM SULPHIDES.

Potassium sulphide (K_2S) is usually obtained by heating potassium sulphate with an excess of carbon. On lixiviating the fused mass and concentrating the solution potassium sulphide ($K_2S.5H_2O$) crystallizes in colorless, deliquescent prisms. It is used extensively in photography, in toning prints, and also in dyeing.

Two companies—Mallinckrodt Chemical Works, St. Louis, Mo., and Smith, Kline & French Co., Philadelphia, Pa.—reported production in 1918 and the figures are included with "all others" in the table on page 389. Nearly all the product contained about 50 per cent of K_2S. Prices ranged from about 30 to 90 cents a pound. No data are available on imports, except that in 1914 the value was less than $100.

Potassium hydrogen sulphide is obtained in solution by passing hydrogen sulphide into a solution of potassium hydroxide. Polysulphides (K_2S_3, K_2S_4, K_2S_5) are obtained by boiling solution of K_2S with free sulphur. Liver of sulphur used in medicine is a mixture of K_2S_3, $K_2S_2O_3$, and K_2SO_4 and is obtained by melting a mixture of potassium carbonate and sulphur.

POTASSIUM SULPHITES.

Potassium sulphite (K_2SO_3) is prepared by dissolving 100 grams of caustic potash in 200 cubic centimeters of air-free water, saturating the solution with sulphur dioxide, adding a further quantity of 100 grams of caustic potash dissolved in a little water, and evaporating the solution in vacuo.

It forms two hydrates—$K_2SO_3.H_2O$ and $K_2SO_3.2H_2O$. It is a strong reducing agent, and solutions readily undergo oxidation in the air. The Mallinckrodt Chemical Co. is the only firm that reported production in 1918, and the figures are included with "all others" on page 389. Available data on imports are shown on page 396.

Potassium bisulphite ($KHSO_3$) is produced when a solution of potassium hydroxide is saturated with sulphur dioxide, and is pre-

[1] Report on the fertilizer industry, p. 115, 1916.

cipitated in needle-shaped crystals by the addition of alcohol. Production in 1918 was reported by only one firm, the Mallinckrodt Chemical Co., St. Louis, Mo., and the figures are included in the item "all others," page 389. The output was about 93 per cent pure and sold at about 52 cents a pound. In 1914, 35,200 pounds of 30 per cent bisulphite liquid, valued at $656, and 185 pounds of crystals, valued at $16, were imported. The value of the crystals corresponds to a little more than 8.6 cents a pound.

Potassium pyrosulphite ($K_2S_2O_5$), known also as metasulphite and metabisulphite, is formed when sulphur dioxide is passed into a hot saturated solution of potassium carbonate and is obtained in crystalline form on cooling the solution. It is employed extensively in photography. No domestic production has been reported to the Geological Survey, but in 1914 considerable quantities were imported listed as metasulphite and metabisulphite, as shown on page 396. The value of the commercial liquid imported was 5 to 6 cents a pound and the value of pure crystals was 12 to 17 cents a pound.

POTASSIUM TARTRATES.

Potassium bitartrate ($KH[C_4H_4O_6]$) is the principal constituent of wine lees, argol, and cream of tartar. Lees is the solid matter collected from the bottom of the vessels in which grape juice is fermented, and argol is the crystalline crust deposited on the sides of the vessels. Lees contain 24 to 32 per cent of tartaric acid and argol 40 to 70 per cent, mostly in the form of potassium bitartrate. Cream of tartar, which consists chiefly of potassium bitartrate, is prepared from argol by recrystallization, and it is often contaminated with starch and other adulterants. Argol is used in assaying, cream of tartar in baking powders, and purified potassium bitartrate in candy, in pharmaceutical preparations, and in the manufacture of tartaric acid and other tartrates. Probably 90 per cent of the bitartrate produced is used in manufacturing baking powder.

Potassium tartrate ($K_2[C_4H_4O_6]$) is obtained by neutralizing potassium hydrogen tartrate with potassium carbonate or hydroxide. It forms colorless crystals freely soluble in water.

Potassium sodium tartrate, or Rochelle salt ($KNa[C_4H_4O_6]$), is obtained by neutralizing potassium bitartrate with sodium carbonate or hydroxide. Its chief use is in medicine, but it now also finds some application in electric intensifiers.

Potassium antimonyl tartrate, or tartar emetic ($KSbO.C_4H_4O_6$-H_2O), is obtained by dissolving antimonious oxide in a solution of potassium bitartrate and crystallizing out the product. It is used in medicine and as a mordant in dyeing.

Statistics of production of tartrates are grouped together and shown on page 389, while data on imports are shown on pages 391, 392, 396. The products were practically pure. The producing firms in 1918 were as follows:

American Cream of Tartar Co., San Francisco, Calif.
Mallinckrodt Chemical Co., St. Louis, Mo.
Chas. Pfizer & Co., New York, N. Y.
Tartar Chemical Works, New York, N. Y.

POTASSIUM THIOCYANATE.

Potassium thiocyanate (KCNS) is formed by heating potassium cyanide and sulphur or by boiling a mixture of potassium ferrocyanide, potassium carbonate, and sulphur, and in other ways. It is used as a chemical reagent and has been used as a refrigerant, but finds very slight application. No production was reported in 1918, and the available data on imports are shown on page 396.

OTHER POTASSIUM SALTS.

Small quantities of other potassium salts are undoubtedly produced in the United States, but none were reported as having been produced in 1918, and no data for other years are available. A list of such salts imported in 1914 is given on page 397.

BIBLIOGRAPHY.

As an extensive bibliography was included in the report on potash for 1917 the present bibliography will be confined practically to papers issued in 1918, except for a few articles omitted from the report for 1917.

PUBLICATIONS ON POTASH ISSUED BY UNITED STATES GEOLOGICAL SURVEY.

1919. Gale, H. S., and Hicks, W. B., Potash: Mineral Resources, 1917, pt. 2, pp. 397–481.

PUBLICATIONS ON POTASH ISSUED BY UNITED STATES DEPARTMENT OF COMMERCE.

The following items on potash were published in 1918 by the Bureau of Foreign and Domestic Commerce of the Department of Commerce in its Daily Consular Reports. These items are based largely on letters that have been received by the bureau, which has made no extended investigations on potash:

1918. German potash production: No. 145, p. 1110, June 21.
German potash imported into Norway: No. 77, p. 31, Apr. 2.
Exports of potash from Germany (1911–1913): No. 216, p. 1006, Sept. 14.
The German potash industry in war time: No. 237, p. 118, Oct. 9.
Dutch view of German potash industry: No. 241, p. 186, Oct. 14.
The economic effect of the loss of Alsace-Lorraine: No. 292, pp. 993–995, Dec. 13.
Proposed regulation of potash mines in Spain: No. 161, p. 130, July 11.
State control of mineral fertilizers in Spain: No. 226, p. 1166, Sept. 26.
Concessions to work Catalonia potash beds: No. 305, p. 1210, Dec. 30.
Great Britain's sources of potash supplies: No. 242, pp. 198–200, Oct. 15.
Potash from seaweed in South Africa: No. 68, p. 1102, Mar. 22.
Production of potash in Chile: No. 103, p. 437, May 2.
Saving of wood ashes for fertilizing in Brazil: No. 75, p. 1228, Mar. 30.
Value of wood ash as a fertilizer: No. 114, p. 613, May 15.

ASPHALT.[1]

By C. C. Osbon.

GENERAL CONDITIONS OF THE ASPHALT INDUSTRY.

Asphalt has long been widely used in making roads, and in recent years many producers of asphalt and related bitumens have succeeded in getting their products extensively employed in the construction of buildings and in other industries. Whether it is used in the manufacture of flooring, roofing, waterproof coating, insulation, mineral rubber, varnish, or paint, asphaltic material has been found satisfactory, and asphalt products are now in great demand among contractors and engineers.

There was a distinct tendency in 1918 toward municipal economy in street paving; many projects involving the construction of new pavement were postponed, and contract work involving asphaltic material was restricted in large measure to the repairing and resurfacing of existing pavements. However, the increased demand for asphaltic material in the construction of highways in the vicinity of military posts, cantonments, and shipyards, in the manufacture of roofing materials for the thousands of temporary and semipermanent buildings that were erected throughout the country in 1918, and for other purposes in war work nearly offset municipal economy, and as a consequence the output of asphalt declined only about 13 per cent.

Although the conditions that existed during the war were adverse to an increase in the output of 1918 over that of 1917, more asphalt was produced in 1918 than in any year preceding the war, and the outlook for the industry is now very encouraging. Restrictions upon the importation of native asphalt and upon the laying of new pavements have been removed. Embargoes on the use of tank cars and coastwise shipping are no longer in effect. The maintenance of many highways throughout the country was neglected during the war; roads were subjected to the strain of unusually heavy motor-truck traffic; plans for new work were held in abeyance; and many an industrial town assumed the proportions of a city. Extensive repairs and new work are therefore immediately necessary, and a large number of contracts have already been awarded.

The conditions in Washington, D. C., which contains more than 350 miles of street pavement and in which asphalt is a popular paving material, are similar to those in many other typical American cities. Plans for street improvement in that city have long been delayed, and it is reported that pavements valued at more than $500,000 were laid in 1919—a new record for Washington.

[1] The statistical tables presented in this report are largely the work of Mrs. Andrena Stratton, Miss A. B. Coons, and J. A. Dorsey.

According to the Department of Agriculture more roads were constructed by the United States Government in 1919 than in any preceding year. Building operations that involve the use of asphalt products have also been resumed on a large scale throughout the country. In view of these conditions, of the many new uses of asphaltic material, and of the fact that producers of asphalt have recently formed a cooperative association for the general welfare of the industry, it seems that the demand for asphalt and related bitumens will correspondingly increase and that a new record will be established.

Despite the curtailment of the imports of native asphalt and of road and building construction in the United States caused by the war, the year 1918 was one of prosperity for the domestic asphalt industry. Although the output was less than that in 1917, the value exceeded that of any preceding year, and the general prosperity was shared by practically all branches of the industry. The most striking development, however, was the large increase in the value of petroleum asphalt produced from imported Mexican oil.

The statistics presented on subsequent pages indicate that the war adversely affected the importation and production of all varieties of asphalt and related bitumens in the United States in 1918 except Mexican petroleum asphalt, ozokerite, and ichthyol and that it stimulated prices for all asphaltic material produced in this country. The favor with which petroleum asphalt has been received in the United States is indicated by the facts that its production from domestic petroleum nearly doubled in the four years preceding 1918 and that the production of petroleum asphalt from imported oil more than doubled in that period. Despite the fact that conditions were unfavorable for the production of asphalt in 1918 and that asphalt is produced from petroleum of grades suitable for fuel, and despite the large requirements of fuel oil for bunker loading at Atlantic ports and for war industries in or adjacent to the Atlantic seaboard in 1918, the output of petroleum asphalt from Mexican oil increased 1 per cent and the output of petroleum asphalt from domestic oil declined only 25 per cent.

The imports of crude native asphalt declined during the war, but the resumption of normal conditions will probably restore this trade to its pre-war proportions.

The domestic ozokerite industry, revived in 1916 by the American Chemical & Ozokerite Co. and fostered by the discontinuance of imports from Galicia, made substantial progress in 1918.

The total number of companies engaged in the production of asphalt and related bitumens in the United States in 1918 was 42. Thirty-two operators contributed to the output of petroleum asphalt, compared with 40 in 1917. Of the operators in 1918, 21 produced asphalt exclusively from domestic petroleum, 9 exclusively from Mexican petroleum, and 2 from oil of both domestic and Mexican origin. California supplied petroleum of asphaltic base to 14 plants, Illinois to 3, Louisiana and Oklahoma to 2 each, and Kansas, Texas, and Ohio to 1 each. Ten plants contributed to the country's supply of bituminous rock, gilsonite, grahamite, ozokerite, and wurtzilite (known to the trade as elaterite) in 1918 as follows: Utah, 4; California, 3; and Kentucky, Oklahoma, and Texas, 1 each. Bituminous

sandstone was produced at 4 of these plants, gilsonite at 3, and bituminous limestone, grahamite, ozokerite, and wurtzilite each at 1. One plant produced both gilsonite and wurtzilite.

PRODUCTION.

The quantity of asphalt and related bitumens produced in the United States in 1918 was 1,237,853 short tons, valued at $18,540,032, a decrease of 191,173 tons, or about 13 per cent, in output but an increase of $2,590,104, or a little more than 16 per cent, in value, compared with the production of 1,429,026 tons, valued at $15,949,928, in 1917. The accompanying tables and figure 63 show that the output and value of asphalt and related bitumens have materially increased in recent years.

PETROLEUM ASPHALT.

The output of the petroleum asphalt industry is assigned to two major classes—solid and semisolid products of less than 200 penetration[1] and liquid products of over 200 penetration. The solid and semisolid products include paving asphalt used in the construction of sheet-asphalt pavements, asphaltic concrete, and asphalt blocks; binder used for direct application to gravel, stone, and concrete pavements and for the maintenance of bituminous macadam and bituminous concrete pavements; filler introduced directly into the joints of block, brick, and stone pavements; and other asphalt used in the manufacture of roofing and waterproofing materials, mineral rubber, insulation, acid-resistant compounds, and mastic. The liquid or soft products include road oil used largely for laying dust; paving, roofing, and waterproofing flux used in softening native asphalt and solid petroleum asphalt; and other asphalt used in saturating felts and in the manufacture of paint, japan, and varnish.

The total output of petroleum asphalt in this country in 1918 was 1,177,819 short tons, a loss of 169,603 tons, or about 13 per cent, compared with 1917. The average price received at the refineries for this material was $15.08 a ton and the gross market value was $17,759,224, a gain of $3.82 in average unit price and of $2,582,720, or 17 per cent, in value over 1917. The foregoing totals include 616,547 tons of solid and semisolid products, valued at $10,346,963, an average of $16.78 a ton, and 561,272 tons of liquid products, valued at $7,412,261, an average of $13.21.

The production in 1918 of petroleum asphalt derived from domestic oil amounted to 527,575 short tons, a loss of 174,234 tons, or nearly 25 per cent, of the output in 1917. The average price obtained for this material was $14.09 a ton and the value of the entire output was $7,435,204, a gain of $3.07 in average sale price, but a loss in value of $299,487, or nearly 4 per cent, compared with 1917. Included in the totals of asphalt derived from petroleum of domestic origin are 278,166 short tons of solid and semisolid products utilized mainly in the paving and roofing industries, valued at $4,371,742—an average of $15.72 a ton; and 249,409 tons of liquid products, com-

[1] The "penetration" is the distance, in hundredths of a centimeter, a No. 2 sewing needle will penetrate into the material in five seconds under a weight of 100 grams at a temperature of 77° F.

prising road oil, flux, and asphaltic paint, valued at $3,063,462—an average of $12.28 a ton. Compared with the price in 1917, the aver-

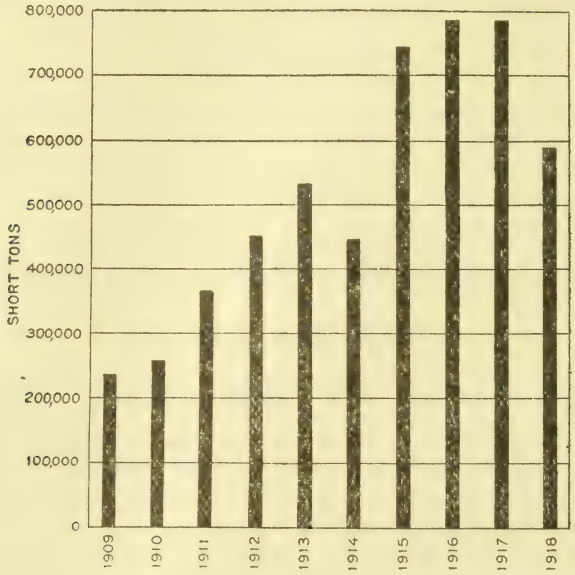

FIGURE 63.—Diagram showing growth of the domestic asphalt industry.

age market price per ton in 1918 of solid and semisolid asphaltic products derived from domestic petroleum was $3.46 higher, and that of the liquid products was $2.34 higher.

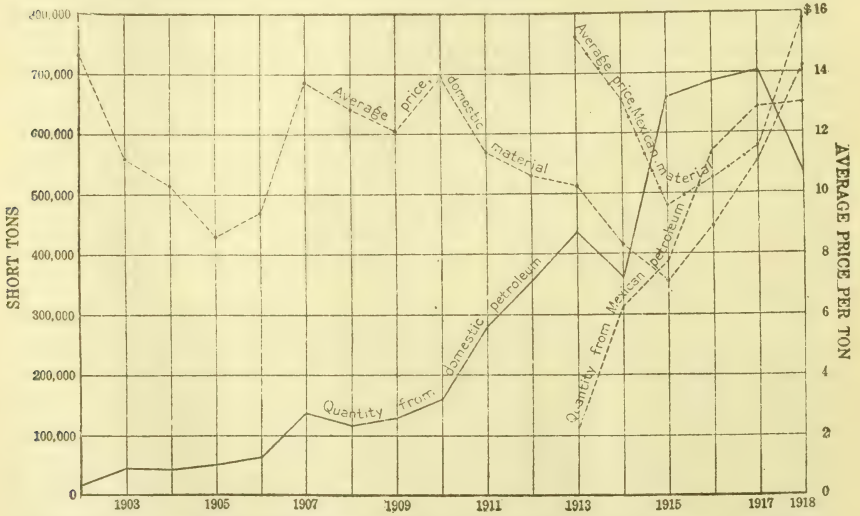

FIGURE 64.—Diagram showing fluctuations in the production and price of petroleum asphalt in the United States, 1902–1918.

The production in 1918 of petroleum asphalt derived from imported Mexican oil amounted to 650,244 short tons—a gain of 4,631 tons, or about 1 per cent, compared with the output in 1917. The

average price received for the material f. o. b. the refineries was $15.88 a ton, and the gross market value was $10,324,020—a gain of $4.35 in average sale price per ton and of $2,882,207, or nearly 39 per cent, in gross market value compared with 1917.

The gross production of Mexican petroleum asphalt includes 338,381 tons of solid and semisolid products, valued at $5,975,221, an average of $17.66 a ton, and 311,863 tons of liquid products, valued at $4,348,799, an average of $13.94 a ton. Compared with the prices received in 1917 for corresponding products those received in 1918 for the solid and semisolid varieties averaged $3.90 a ton higher and those received for the liquid varieties $4.87 a ton higher.

The accompanying diagrams show graphically the growth of the domestic asphalt industry and the fluctuations in the production and price of petroleum asphalt in the United States.

Asphalt produced from domestic petroleum, 1902–1918.

Year.	Quantity (short) tons).	Value.	Year.	Quantity (short) tons).	Value.	Year.	Quantity (short tons).	Value.

1915	388,318	3,730,436	1918	650,244	10,324,020

NATIVE ASPHALT AND RELATED BITUMENS.

According to reports received by the Geological Survey the quantity of native asphalt and related bitumens, including bituminous rock, gilsonite, grahamite, ozokerite, and wurtzilite produced from mines and quarries in the United States in 1918 was 60,034 short tons, a quantity less by 21,570 tons, or about 26 per cent, than the output of similar materials in 1917. The average price received for this material at the source of production was $13.01 a ton, and the market value of the entire output was $780,808, a gain of $3.53 a ton in average unit price and of $7,384, or 1 per cent, in gross market value, compared with 1917. At the mines bituminous rock sold in 1918 for an average price of $3.64 a ton, gilsonite for $19.67 a ton, grahamite for $7 a ton, ozokerite for 61 cents a pound, and wurtzilite for $60 a ton. An analysis of statistics of production in 1917 and 1918 shows losses in 1918 in the output of all the native asphalts and related bitumens except ozokerite, which gained more than 100 per cent. The data relating to bituminous rock are incomplete. It is believed that the resumption of normal conditions will

increase the production of bituminous rock and of gilsonite. Gilsonite is in demand as a base for marine paints and protective coatings for steel work and for use in the manufacture of automobile tires and other rubber products. The decreased output of grahamite and wurtzilite in 1918 was due to the high cost of mining and marketing these minerals and to their inability to compete with certain grades of petroleum asphalt.

Native asphalt and related bitumens produced in the United States, 1882–1918.

Year.	Quantity (short tons).	Value.	Year.	Quantity (short tons).	Value.	Year.	Quantity (short tons).	Value.

a Wurtzilite produced in Utah included in "Other States."
b Includes Kentucky, Oklahoma, and Texas.

CONDITIONS IN PRINCIPAL STATES.

California.—California, as in other recent years, led all the States in the production of domestic petroleum asphalt, its output in 1918 from 14 refineries aggregating 195,275 short tons, a decrease of 25,019, or 11.4 per cent, compared with 1917. This quantity includes solid, semisolid, and liquid products used in paving and in the manufacture of roofing and asphaltic paint. The decrease noted was unquestionably due to the steady appreciation in the value of fuel oil, at the expense of which a part at least of the petroleum asphalt produced in California is made.

As a consequence of increased costs of labor at the quarries and of the competition afforded by the 14 refineries producing petroleum asphalt in the same State, activity in the mining of bituminous rock in California was materially diminished in 1918. The output, which was only 3,260 short tons, valued at $12,516, was produced by three companies and consisted of bituminous sandstone quarried in Santa Barbara, Santa Cruz, and San Luis Obispo counties and used in road paving.

Illinois.—Three refineries operating on petroleum produced in the Illinois field manufactured in 1918 100,952 short tons of petroleum asphalt, valued at $1,315,001. Illinois ranked third in the quantity of petroleum furnished to the asphalt industry.

Oklahoma.—The contribution of Oklahoma to the supply of asphalt in 1918 was made by three operators and consisted of 112,232 short tons of petroleum asphalt, valued at $1,357,676, an average price of $12.10 a ton, and of a small output of grahamite mined by the Fort Smith Asphalt Co. in Pushmataha County and used in the manufacture of roofing. Extensive operations were begun in Murray County in 1918 by the Continental Asphalt Co., of Oklahoma City, and though the production of this company did not reach large proportions in that year, it controls a deposit of good bituminous limestone and is preparing to market this product in large quantities. Oklahoma ranked second in the quantity of pertoleum furnished to the asphalt industry.

Utah.—The contribution of Utah to the asphalt industry of the United States in 1918 consisted wholly of bitumens and pyrobitumens. The production in that year aggregated 31,072 short tons, valued at

$663,258, and consisted of gilsonite from Uinta County, ozokerite from Wasatch County, and wurtzilite from Carbon County. The demand for gilsonite was strong, and shipments of this bitumen, though slightly less than those in 1917, amounted to 30,848 short tons, valued at $606,639. Only one company produced wurtzilite in 1918, and the output was small. The output of ozokerite in 1918 was 74,000 pounds, valued at $45,399, compared with 36,000 pounds, valued at $1,000, in 1917.

The interest in oil shale in northeastern Utah monopolized the attention that is normally directed to the expansion of markets for the other hydrocarbon minerals with which Utah is so richly endowed and to the improvement of facilities for satisfying those markets, and no new properties were opened in 1918.

In 1918, as in 1917, extensive experimental work was done in northeastern Utah with a view to producing crude petroleum from bituminous shales.

Other States.—The Geological Survey is unable to show the quantity of petroleum asphalt produced in 1918 from oil of Kansas, Louisiana, Ohio, and Texas grades or the output of native asphalt and related bitumens in Kentucky, Oklahoma, and Texas, without disclosing the operations of individual companies. The total quantity of petroleum asphalt produced in 1918 from oil furnished by the former group of States was 119,116 short tons, valued at $2,165,684, and the output of native bitumens and related materials in the latter group was 25,702 short tons, valued at $105,034. One company produced solid asphaltic material from Kansas petroleum in 1918. The production of asphaltic material in Kentucky in 1918, as in 1917, was restricted to one property in Edmonson County operated by the Kentucky Rock Asphalt Co. The entire output consisted of bituminous sandstone which was used in the paving of city streets and country roads. Two companies produced asphalt from Louisiana petroleum in 1918. Petroleum imported from Mexico was also extensively used in Louisiana in the manufacture of asphalt. The Craig Oil Co., of Toledo, Ohio, contributed a substantial quantity of asphaltic flux produced from Lima-Indiana oil to the country's supply of asphalt in 1918. No deposits of native asphalt in Ohio are known. The contribution of Texas to the output of asphaltic material consisted of petroleum asphalt manufactured from Texas crude oil and of bituminous limestone quarried from a deposit near Cline, Uvalde County, by the Uvalde Rock Asphalt Co., and used in road and street paving.

In addition to the production already mentioned in this section the following States contributed to the output of refined asphalt in 1918 through refineries treating asphaltic oils produced in other States or imported from Mexico as well as crude native asphalt imported from Trinidad and Venezuela: Iowa, Indiana, Maryland, New Jersey, New York, Ohio, Pennsylvania, Rhode Island, and Virginia.

Although Arkansas contains deposits of asphalt and an experiment in paving the streets of Little Rock with asphaltic material from Pike County was made several years ago, there was no commercial production in 1918.

Some of the richest oil shale in the United States is found in western Colorado, and considerable experimental work with a view to producing asphaltic material from it was done in 1918. However, there was no commercial production in that year.

IMPORTS.

NATIVE ASPHALT.

Native asphalt imported for consumption in the United States, 1913–1918.

Year.	Crude.		Dried or advanced		Bituminous limestone.		Total.

The foregoing tables show that the West Indies and Venezuela are the principal foreign contributors to the supply of native asphalt in the United States. The quantity of asphaltic material imported for consumption in this country in 1918 was 114,725 short tons, valued at $627,495, a decrease of 73,161 tons, or nearly 39 per cent, in volume, and of $365,620, or 37 per cent, in value. It is apparent that imports of asphaltic material from all countries except Canada and Mexico declined materially in 1918. This condition is ascribed chiefly to the shortage of shipping and to the consequent curtailment of imports in that year, and in part to the competition of domestic and Mexican petroleum asphalt. It is believed that imports will increase in 1919.

OZOKERITE AND OTHER MINERAL WAXES.

The following table shows the receipts from foreign sources of mineral wax, including ozokerite, ceresine, and various compounded products, of which these waxes form the base, entered for consumption in the United States during the last six years:

Ozokerite and other mineral waxes imported for consumption in the United States, 1913–1918.

Year.	Quantity (pounds).	Value.	
		Price per pound.	Total.
1913	7,141,514	$0.077	$549,992
1914	8,191,529	.061	498,695
1915	2,795,256	.075	210,019
1916	3,007,676	.065	196,185
1917	899,405	.101	90,510
1918	1,809,459	.082	147,805

The following scale of wholesale "spot" prices for ozokerite and other mineral waxes was in effect in the New York market at the end of 1918:

	Cents per pound.
Ozokerite, crude brown	35–36
Ozokerite, black, 164° F	60–61
Ozokerite, 182° F	78–79
Montan wax, crude	35–36
Ceresine, yellow	16–18
Ceresine, white	18–25

Because of the scarcity of supply other varieties of mineral wax were quoted as nominal.

ICHTHYOL.

The following table, compiled from the records of the Bureau of Foreign and Domestic Commerce, shows the quantity and value of ichthyol and ichthyol substitutes imported for consumption in the United States during the last six years.

At the beginning of 1918 prices for true ichthyol in the New York market ranged from $30 to $36 a pound, but were nominal throughout the greater part of the year. Prior to the war the world's supply of ichthyol came from deposits of asphaltic material in Austria.

Ichthyol and ichthyol substitutes imported for consumption in the United States, 1913–1918.

Year.	Quantity (pounds).	Value.	Year.	Quantity (pounds).	Value.
1913	58,485	$83,034	1916	116,738	$93,762
1914	61,416	86,415	1917	58,397	36,232
1915	24,921	28,560	1918	65,752	39,452

EXPORTS.

The export trade of the United States in 1918 in unmanufactured asphalt decreased about 26.6 per cent in quantity but only 1.6 per cent in value, compared with 1917. The value (quantity not available) of asphalt products, including roofing compounds and asphalt-saturated fabrics, exported in 1918 exceeded the value of the unmanufactured asphalt exported in that year, but was 1.5 per cent less than the value of asphalt products exported in 1917.

The following tables were compiled from the records of the Bureau of Foreign and Domestic Commerce, Department of Commerce:

Asphalt exported from the United States, 1913–1918.

Year.	Unmanufactured.		Manufactures of (value).	Total value.
	(Quantity long tons).	Value.		
1913	58,550	$1,267,625	$411,786	$1,679,411
1914	37,246	845,838	401,182	1,247,020
1915	38,203	735,952	438,685	1,174,637

CONSUMPTION.

The quantity of asphaltic and allied material actually consumed in the United States is not susceptible of accurate determination on the basis of the statistics collected by the Geological Survey. The sum of the quantity produced from domestic deposits and manu-

factured from domestic and Mexican petroleum plus the quantity imported, less the quantity exported in a given year, provides, however, an approximation of the quantity consumed that is not without value in the absence of more specific data. The following table shows the approximate quantity of asphalt and related bitumens available for consumption in the United States in 1918, it being assumed that stocks vary little from year to year:

Asphalt and related bitumens produced and imported in the United States in 1918.

Variety.	Production.		Imports.		Total.	
	Quantity (short tons).	Value.	Quantity (short tons).	Value.	Quantity (short tons).	Value.

Exports of unmanufactured asphalt from the United States in 1918 aggregated 22,108 short tons. On the foregoing basis the consumption of asphaltic material in the United States during the last four years is shown by the following table:

Asphaltic material consumed in the United States, 1915–1918.

	Short tons.
1915	1,225,447
1916	1,467,657
1917	1,587,284
1918	1,331,408

The estimated quantity of asphaltic material consumed monthly in the United States during the first six months of 1918 is indicated by the following table of sales and by the accompanying diagram (fig. 65) prepared by the Joint Information Board on Minerals and Derivatives. As the diagram was based upon a preliminary estimate made early in the year 1918 it does not agree in all

respects with preceding statistics. Figures in this diagram showing production and sales relate only to solid and semisolid petroleum asphalt.

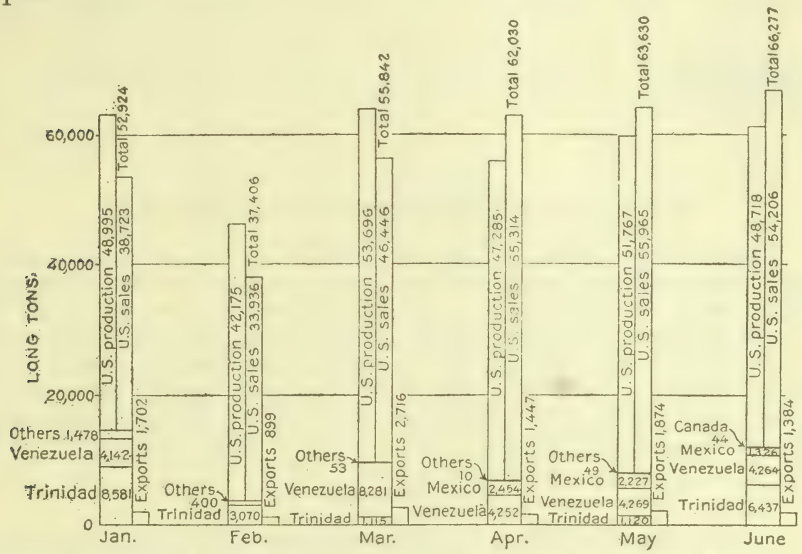

FIGURE 65.—Diagram showing production, imports, exports, and sales of asphalt and related bitumens in the United States during the first six months of 1918.

Asphalt and related bitumens sold in the United States during the first six months of 1918, by months and varieties, in short tons.

Variety.	January.	February.	March.	April.	May.	June.	Total.
Petroleum asphalt:							
Solid and semisolid products	43,370	38,008	52,019	61,952	62,681	60,711	318,741
Liquid products [a]	28,409	31,322	51,549	52,210	56,332	48,829	268,651
Total petroleum asphalt	71,779	69,330	103,568	114,162	119,013	109,540	587,392
Bituminous rock	2,395	3,201	1,214	11,293	1,086	2,820	22,009
Other native bitumens and pyrobitumens	4,001	3,684	2,834	2,511	2,577	2,539	18,146
Grand total	78,175	76,215	107,616	127,966	122,676	114,899	627,547

[a] Includes products sold or used for fuel as follows, in short tons: January, 7,538; February, 9,201; March, 24,120; April, 15,970; May, 10,694; June, 10,154; total, January to June, inclusive, 77,677.

STOCKS.

Stocks (incomplete) of domestic and Mexican asphalt and related bitumens in the United States at the end of each month during the first half of 1918, by varieties, in short tons.

Variety.	January.	February.	March.	April.	May.	June.
Petroleum asphalt:						
Solid and semisolid products	107,264	117,687	126,187	115,804	116,137	110,606
Liquid products	52,915	49,479	53,515	45,882	41,575	38,499
Total petroleum asphalt	160,179	167,166	179,702	161,686	157,712	149,105
Bituminous rock	5,000	5,000	5,000	5,000	5,000	5,000
Other native bitumens and pyrobitumens	1,227	1,699	1,889	1,728	1,014	856
	166,406	173,865	186,591	168,414	163,726	154,961

Stocks (incomplete) of domestic and Mexican asphalt and related bitumens in the United States on Dec. 31, 1918, by varieties, in short tons.

Variety.	Domestic.	Mexican.	Total.
Petroleum asphalt	50,567	67,555	118,122
Bituminous rock			
Gilsonite	1,925		1,925
Ozokerite and wurtzilite	151		151
	52,643	67,555	120,198

OCCURRENCE, PROPERTIES, AND USES.

Owing to the increased interest in the larger use of asphalt and in order that prospective producers and users may be fully informed of the value of asphalt and related bitumens as a raw material from which many useful products may be manufactured, a brief discussion of the occurrence, distribution, properties, and uses of asphaltic material is given herewith. Much of the information presented is based upon the work of Abraham, Richardson, Northrop, Eldridge, Hubbard, and others, and liberal use has been made of their experiments.

DEFINITIONS.

The following definition, adopted in substance and promulgated by the American Society for Testing Materials, has been generally indorsed in this country:

> The term "asphalt" comprises solid or semisolid native bitumens, bitumens obtained by refining petroleum, and bitumens obtained by combining native petroleum bitumens with petroleum or its derivatives, consisting largely of complex cyclic or bridge hydrocarbon compounds fusible upon the application of heat.

The raw materials of the asphalt and allied industries of the United States consist of petroleum, of native asphalt relatively pure or associated with mineral matter, and of ozokerite, gilsonite, grahamite, and wurtzilite. According to the organic theory, petroleum is a mineral oil produced by geodynamic forces from certain types of organic débris. Native asphalt is a bitumen resulting from the metamorphosis of asphaltic petroleum. It occurs both in a relatively pure state and in combination with various proportions of sandstone, limestone, shale, and other rock. If the inorganic mineral content is large, it is called bituminous rock. Ozokerite is a native mineral wax resulting from the metamorphosis of paraffinaceous petroleum; refined ozokerite is called ceresine. Gilsonite and grahamite are asphaltites derived from petroleum. Gilsonite is one of the purest known hydrocarbons, but grahamite often contains a large proportion of inorganic impurities. Both fuse at a higher temperature than asphalt. Wurtzilite is an asphaltic pyrobitumen that yields bitumens on destructive distillation and like them is derived from petroleum. Other bituminous substances are known to exist in this country, but they are of no present commercial importance. There are no well-defined lines of demarcation between some of the types of asphaltic material and allied substances. Each class grades into another, and specimens are frequently found that have characteristics common to more than one variety.

The nomenclature of the important raw materials of the domestic asphalt and allied industries is given in the following table, which follows roughly the classification used by Abraham in "Asphalt and allied substances."

Raw materials of the asphalt and related industries of the United States.

Genus.	Species.	Member.
Bitumens.	Petroleum.	Asphaltic. Mixed base. Paraffinaceous.
	Native asphalt.	Relatively pure. Relatively impure (bituminous rock).
	Asphaltites.	Gilsonite. Grahamite.
	Native mineral wax.	Ozokerite.
Pyrobitumens.	Asphaltic pyrobitumens.	Wurtzilite (trade name elaterite). Asphaltic pyrobituminous shales.

ORIGIN.

Deposits of asphalt and related bitumens are found in the United States in strata of all systems from the Ordovician to the Recent. The oldest formations have been observed in Oklahoma, and the youngest, which consist of sand impregnated with bitumen of earlier origin, occur near Carpinteria, Calif., though small superficial deposits of brea are well distributed throughout the country. Bitumens and pyrobitumens occur in seepages, springs, lakes, subterranean "pools," impregnated rocks, and veins, though seepages and springs rarely yield asphaltic material of commercial value. Petroleum accumulates in porous sandstone and limestone underlain and overlain by more or less impervious rock in upfolds, downfolds, and other structural features called anticlines, synclines, monoclines, domes, and terraces. Like some of the varieties of asphalt, petroleum is found in strata of all systems from Cambrian to Quaternary, but the most prolific sources are in strata of the Carboniferous and Tertiary.

The formation of asphalt, related bitumens and pyrobitumens presupposes the existence of petroleum containing asphaltic hydrocarbons, and that of ozokerite presupposes the existence of paraffinaceous petroleum. It is apparent from Plate IV and from the foregoing discussion that the deposits of asphalt and petroleum in this country are closely related both geographically and stratigraphically. Though there is some difference of opinion concerning the origin of petroleum, it is well established that when once formed it is slowly changed by geodynamic forces into asphalt and other bituminous substances, if conditions are favorable. Crude petroleum contains a large percentage of hydrogen and simple hydrocarbons. When it is subjected to heat and pressure under favorable conditions a large volume of hydrogen is eliminated, resulting in the enrichment of the

residual hydrocarbons and their conversion into more complex compounds both chemically and physically. This is the metamorphic process. According to Richardson[1] colloidal clay accelerates the process by acting as a catalyzer. As the result of studies of the famous pitch lake in Trinidad, British West Indies, he concludes that petroleum is converted into asphalt by emulsification with clay, sand, and water by means of natural gas at high pressure. Maltha and other soft asphalts, hard asphalt, the asphaltites (gilsonite and grahamite), the asphaltic pyrobitumens (elaterite and wurtzilite), and asphaltic pyrobituminous shales are probably successive stages in the metamorphosis of asphaltic petroleum. If the petroleum is of paraffin base, ozokerite and other mineral waxes are sometimes formed.

DISTRIBUTION.

The known deposits of asphalt and related bitumens in this country, somewhat like the areas in which crude petroleum is produced, may be roughly assigned to four major regions (see Pl. IV), as indicated in the following table:

Deposits of asphalt and related bitumens in United States.

Region and variety.	State.	County.
Appalachian.		
Pure native asphalt	Kentucky	Breckenridge and Grayson.
Bituminous rock	do	Breckenridge, Carter, Edmonson, Grayson, Logan, and Warren.
Grahamite	West Virginia	Ritchie.
Mid-Continent.		
Pure native asphalt	Arkansas	Pike.
Bituminous rock	do	Pike and Sevier.
Impsonite	do	Scott.
Bituminous rock	Missouri	Lafayette.
Pure native asphalt	Oklahoma	Carter and Murray.
Bituminous rock	do	Atoka, Carter, Comanche, Garvin, Jefferson, Johnson, Le Flore, Love, McCurtain, Marshal, Murray Pontotoc, and Stephens.
Grahamite	do	Atoka, Pushmataha, and Stephens.
Impsonite	do	Le Flore and Murray.
Bituminous rock	Texas	Burnet, Montague, and Uvalde.
Rocky Mountain.		
Grahamite	Colorado	Grand.
Impsonite	Nevada	Eureka.
Pure native asphalt	Utah	Box Elder and Uinta.
Bituminous rock	do	Carbon, Grand, Uinta, and Utah.
Gilsonite	do	Uinta.
Wurtzilite	do	Do.
Ozokerite	do	Utah and Wasatch.
California.		
Pure native asphalt	California	Kern, San Luis Obispo, and Santa Barbara.
Bituminous rock	do	Mendocino, Monterey, Orange, San Luis Obispo, Santa Barbara, and Santa Cruz.

The richest and most extensive deposits of asphalt and related bitumens in this country are found in Oklahoma, though Utah contains the largest variety. Small deposits of asphaltic material occur in Alabama, Illinois, Indiana, and Louisiana, but they have not been

[1] Richardson, Clifford, The nature and origin of petroleum and asphalt: Met. and Chem. Eng., vol. 16, No. 1, p. 25, 1917.

MAP OF THE UNITED STATES SHOWING DISTRIBUTION OF ASPHALT, PETROLEUM, AND RELATED BITUMENS

After Eldridge and others

commercially developed. Asphaltic pyrobituminous shale is found in Wyoming, Colorado, Utah, and other States, but it has never been used commercially as a source of asphalt.

The following quotation[1] shows the general geographic distribution and stratigraphic range of asphalt and related bitumens in the United States:

The distribution of asphalts and bituminous rocks in the United States is wide. The asphaltites are found in West Virginia, Oklahoma, and Utah; bituminous limestones in Oklahoma, Texas, and Utah; bituminous sandstones in Kentucky, Missouri, Oklahoma, Texas, Utah, and California;[2] earthy bitumen of great purity, occurring as veins, in California; brea, it is possible, occurs in all petroleum areas, but in the present investigation it was found only in Oklahoma, Wyoming, and California, although small bodies are reported to occur in Montana. The localities of these several occurrences are shown on the general map of the United States (Pl. IV).

The stratigraphic range of the bitumens and their compounds is as wide as their geographic distribution. Their oldest association observed is with the Ordovician shale of the Tenmile region in eastern Oklahoma, where impsonite, an asphaltite closely related to albertite, occurs in vein form. Other veins of like material, as well as a bituminous sandstone, occur in the series of Ordovician sandstone overlying the shales along the Oklahoma-Arkansas line. In central Oklahoma, in the Buckhorn district, are other bituminous sandstones, also of Ordovician age, though perhaps not to be correlated with the foregoing. Above these, in direct succession, is the summit limestone of the Ordovician, at least for this locality—a massive bed of variable thickness the maximum being approximately 400 feet. The entire body of the rock is varyingly impregnated with bitumen, the more highly enriched portions to an average of 6 to 8 per cent. In this same locality the lower coal measures also, at one or more horizons, are richly infiltrated with bitumen, one of their limestones carrying an average of 14 per cent. The lower coal measures are unconformable with the underlying formations, and the occurrence of bitumen at the several horizons suggests a common source and origin for it, and an inflow to its present reservoirs, perhaps subsequent to the laying down of all the sediments involved, if not, indeed, subsequent to their folding. On the other hand, from the presence in the coal measure conglomerate of an occasional pebble, believed to be of Ordovician bituminous sandstone, particularly observed by Mr. Taff, there may have been two or more distinct flow periods.

West and south of the Arbuckle Mountains the coal measures again carry bitumen in some of their members—grits and limestones. These horizons, however, may be quite different from those in the Buckhorn region.

In the vicinity of Higginsville, Mo., the Warrensburg sandstone, occupying what Mr. Arthur Winslow, the State geologist, considers a channel of erosion in the coal measures, but assigned to the Carboniferous, is also infiltrated with bitumen to about 6 per cent.

In West Virginia the grahamite vein, which has brought much renown to the region of its occurrence, occupies a vertical fissure in the Waynesburg sandstone and adjoining beds above and below horizons in the upper productive and upper barren coal measures of the Carboniferous age.

The bituminous sandstones of Kentucky are closely successive members of the Chester formation and the basal portion of the coal measures, and all, at one point or another, are impregnated to a degree sufficient to render them economically available for paving purposes, their contents ranging between 5 and 8 per cent.

The Permian, or what is at present accepted as the Permian, in central Oklahoma has been penetrated by fissures through which petroleum has risen into its superficial sandy members, and has also been converted to brea as surface deposits. This occurs at Wheeler, a settlement about 40 miles west of Ardmore. The locality is practically that of the enriched coal measure sandstones south of the Arbuckle Mountains, and there is little doubt that a common source supplied all the different horizons that now constitute the exposed storage reservoirs of the former fluid petroleum.

---

[1] Eldridge, G. H., The asphalt and bituminous rock deposits of the United States: U. S. Geol. Survey Twenty-second Ann. Rept., pt. 1, pp. 227–231, 1901.

[2] Since the writer's field investigation indefinite accounts of bituminous sandstones in Alabama and Illinois have appeared in certain newspapers.

The Trinity sand of the Lower Cretaceous is a bitumen-bearing formation at many points in its area of outcrop in southern Oklahoma and northern Texas. This is particularly the case where it rests upon the Carboniferous, an occurrence that is significant of the derivation of its bitumen from a source perhaps identical with that from which the several members of the coal measures have derived theirs.

The Glen Rose formation, also a member of the Trinity division of the Lower Cretaceous, in one of its limestones carries the bitumen of the deposits of Post Mountain, near the town of Burnet, Burnet County, Tex. The Anacacho formation of the Texas Upper Cretaceous, corresponding to a horizon near the base of the Montana of the Rocky Mountain section, carries the rich bituminous limestones extensively quarried in the vicinity of Anacacho Mountain, 18 miles west of Uvalde, in southern Texas. In this connection the presence of important oil horizons in the Montana formation of the Florence oil field in Colorado is not unworthy of note.

The Middle Park formation of Middle Park, Colo., largely a terrane of eruptive material and a correlative of the Denver of the plains—a formation for the present termed post-Laramie, without assignment to Cretaceous or Tertiary—also carries bitumens. The deposit occurs in the northern portion of Middle Park, almost in the heart of the Rocky Mountains. It is here an asphalt resembling gilsonite and occupying an irregular fissure or series of fissures in the clays, sandstones, and conglomerates of the formation referred to. The occurrence is, so far as known, limited to the immediate region in which it is found, and is thus comparatively isolated, the nearest asphalt being the gilsonite found along the Colorado-Utah line, 150 miles distant.

The bitumens of the Tertiary horizons are apparently confined to the West—to Colorado, Utah, and California. The various divisions of the Eocene in eastern Utah and just across the line in Colorado are noted both for the variety of their asphalts and for the size of their veins. It is in this region, of the White and Green Rivers and the celebrated Book Cliffs, that the great veins of uintaite are found and that the minor seams of wurtzilite, ozokerite, and nigrite occur. Bituminous limestones are also of wide distribution, though confined to the Green River shales. The asphaltites occur in fissures both in this formation and in those overlying, especially the Bridger and Uinta. Maltha springs also occur, and even petroleum is reported in one of the upper members of the Cretaceous, a few miles east of the Utah-Colorado line. The Green River shales are noted throughout the West for their bitumen contents, and it is surmised that they are the source of the asphalts, at least, of this vast area. The variation in the ultimate material as it to-day fills one fissure or another is perhaps due in part to a change somewhat allied to fractional distillation in petroleum technology and in part to the degree to which oxygen absorption has been carried on. In any event, the variety of bitumen found can hardly excite wonder when considered as to the origin of the material and the differentiations that take place in artificial distillation. It is, indeed, to be expected.

The occurrence of bitumens in the Neocene is confined to California. The rocks of this period here embrace a heavy series of shales with local sandstone, tuffs, etc.—The Monterey formation; a conspicuous body of massive sandstones with a minor proportion of shales known as the San Pablo formation, but in doubt as to its position as a member of the Miocene or Pliocene, and hence in the region of its occurrence regarded as Middle Neocene; and a succession of sandstones, conglomerates, and clays, probably Pliocene, but for the present termed Upper Neocene, with the specific name Paso Robles assigned to it.

In addition to the foregoing there are certain and important sandstones and sand aggregates of somewhat doubtful age, but where encountered seeming to lie beneath the shales of the Monterey rather than in them, and often against and upon granite. Such is their occurrence in the vicinity of Santa Cruz, and again at one or two points in the range bordering the Salinas Valley on the east. These sandstones are locally heavily impregnated with bitumen, and near Santa Cruz are extensively quarried for paving purposes in San Francisco and elsewhere.

The Monterey formation is of particular importance, in that for almost the entire length of the State its terrane is more or less conspicuously marked with petroleum or maltha seepages, while its sandy members may appear as minor storage reservoirs of oil, this now altered at the outcrop to a material of pasty consistency, and forming with the sand grains an asphaltic compound of considerable richness. Such sandy beds occur at Point Arena, in the San Antonio Val-

ley, and in the region of the Sisque. The shales of the Monterey are not only generally bituminous, but some of their more arenaceous and porous members are also especially rich, doubtless having received an inflow of petroleum from their adjoining and less open associates. It is in the shales of the Monterey, too, as well as in the Middle Neocene, that veins of the more solid bitumens, mixed with clastic material derived from the country rock, are found. Except for the clastic material, the bitumen would resemble in structure the asphaltites, though still differing from them in other features. Veins of this description are conspicuous in the vicinity of Santa Maria, Santa Barbara, and Asphalto. Near the latter place the asphaltic material is intimately related to, even associated with, petroleum.

The San Pablo formation, at least that portion of it in the San Luis Range, has been converted into a vast storage reservoir. It is the surface terrane over an area of nearly 50 square miles a short distance southwest of San Luis Obispo, and perhaps half its outcrop here shows impregnation with bitumen in greater or less degree, locally to a high degree. In the same region scattered bodies of the Paso Robles formation have also been infiltrated where resting on the San Pablo or the Monterey.

The San Pablo is also, perhaps, represented in the region of the Sisque, 40 miles southeast of Santa Maria, where along the southern base of the San Rafael Range is a highly enriched body of sandstone, of doubtful correlation from its structural association with recognized Monterey sandstones, but possibly of the age suggested. It is locally one of the richest sandstones in California.

In the region of the Graciosa Hills, 6 to 10 miles south of Santa Maria, there rests upon the Monterey, unconformably, a heavy body of loosely coherent sands or sandstone commonly regarded as Pliocene. Cracks have developed in the formation, which have been filled with bitumen carrying from 30 to 60 per cent of elastic matter. The material resembles in general appearance that already referred to as of vein form in the Middle Necocene near Asphalto. Here, however, it has not yet been found in association with petroleum.

Post-Pliocene sandstones are found with small gash veins and other irregular but more or less extensive bodies of the solid bitumens in the region of More's Landing, 7 miles west of Santa Barbara. A material in many ways resembling gilsonite was found as a minute pocket in the sandstone, but the mass of the bitumen is of the solid variety, mixed with 20 to 30 per cent of clastic material. Twelve miles east of this occurrence is the important petroleum-producing region of Summerland. Pleistocene or recent sands have been heavily charged with bitumen at Carpinteria, 12 miles east of Santa Barbara. They have been for the most part removed, but the continuous flow of maltha in the floor of the quarry would quickly impregnate an equal body were the excavation to be filled with fresh sand from the adjoining ocean beach.

Superficial deposits of brea are well distributed over the United States. Those observed by the writer were in Oklahoma, Wyoming, and California, the first no longer increasing from active springs, the others still forming. The source of their malthas is naturally extremely varied. In addition to the above there are doubtless many others of but little less importance scattered through the oil regions of the country.

Detailed data concerning the occurrence of asphalt and related bitumens in this country are given in the report quoted above and in a book by Herbert Abraham.[1]

The principal sources of petroleum asphalt are the semiasphaltic oils produced in Illinois and Oklahoma and the asphaltic oils produced in California, Louisiana, and Texas. (See Pl. IV.) The following quotation [2] explains the general location of the areas in which petroleum is produced in the United States:

The areas in which crude petroleum is produced in the United States are assigned to nine major fields. This division, though mainly geographic, incidentally expresses to a considerable degree differences in the characteristics of the oil produced.

[1] Asphalt and allied substances, New York, D. Van Nostrand Co., 1918.
[2] Northrop, J. D., Our mineral supplies—Petroleum: U. S. Geol. Survey Bull. 666–DD, pp. 4–8, 1918.

1. The Appalachian field includes all areas of oil production in southwestern New York, western Pennsylvania, eastern Ohio, West Virginia, Kentucky, and Tennessee. The crude oils produced in this field range in gravity from 25° to 50° Baumé, are in the main of paraffin base, are free from asphalt and objectionable sulphur, and yield by ordinary refining methods relatively high percentages of gasoline and illuminating oils.

2. The Lima-Indiana field embraces the areas of petroleum production in western Ohio and in Indiana. The product of this field ranges in gravity from 30° to 35° Baumé and is of paraffin base, though containing a small proportion of asphalt.

3. The Illinois field includes the principal area of oil production in the southeastern part of Illinois, as well as a number of scattered pools of small individual extent in the central and western parts of the State. The oil in this field ranges in gravity from 28° to 40° Baumé and contains varying proportions of both asphalt and paraffin. * * * Aside from minor pools that may be discovered from time to time in the western part of the State, the productive oil territory in this field is believed to be now under development.

4. The Mid-Continent field includes all areas in which petroleum is produced in Kansas and Oklahoma. The oils of this field vary in composition within wide limits, ranging from asphaltic varieties that are lean in gasoline and illuminants to high-grade paraffin oils that yield a large percentage of the lighter products of distillation. The range in gravity is between 27° and 42° Baumé. Although this field is believed to have attained its maximum annual production, amounting to 115,809,792 barrels, in 1916, it is destined to remain the principal contributor to the petroleum supply of the country for many years, as its productive districts are only partly drilled, and its boundaries embrace large areas of untested and apparently not unfavorable territory.

5. The north Texas field includes a number of detached areas of oil production in the northern and east-central parts of Texas. The oils produced are in general similar to those of the Mid-Continent field, with the exception of that obtained in the Powell pool, Navarro County, which has a gravity of about 23° Baumé and is of little commercial value except as a fuel.

6. The north Louisiana field includes the areas of petroleum production in Caddo, De Soto, Bossier, Red River, and Sabine parishes. The oils of this field range in gravity from 22° to 42° Baumé and are of paraffin base, though containing ordinarily small percentages of asphalt.

7. The Gulf field includes a large number of detached oil pools associated with saline domes in southeastern Texas and southern Louisiana. Oils from the Gulf field, though variable in composition, are characterized by relatively high percentages of asphalt and low percentages of the lighter distillation products. In general they range in gravity between 15° and 28° Baumé and contain considerable sulphur, much of which is in the form of sulphureted hydrogen and is easily removed by steam before the oil is utilized. The low-gravity oils from this field are used chiefly as fuel and for the manufacture of asphalt and asphalt products. The lighter grades are refined and yield lubricating oils of superior quality.

8. The Rocky Mountain field includes all areas of petroleum production in Colorado, Wyoming, and Montana, as well as areas of prospective oil production in Utah and New Mexico. Crude oils from this field are in the main of paraffin base and yield relatively high percentages of gasoline, illuminating oils, lubricants, and fuel distillates. The greater part of the oil produced ranges in gravity from 32° to 48° Baumé and contains little or no objectionable sulphur. Heavy asphaltic oils, ranging in gravity from 18° to 24° Baumé, suitable chiefly for fuel or for the manufacture of asphalt, are obtained in certain parts of this field.

9. The California field embraces all areas of oil production in that State. The oils of this field are in the main of asphalt base and range in gravity from 12° to 35° Baumé. Relatively small quantities of paraffin-base oils are found in certain localities. About 25 per cent of the petroleum produced in California is used for fuel or for the manufacture of asphalt and asphalt products.

PROPERTIES.

Asphalt and its related bitumens and pyrobitumens consist chiefly of carbon and hydrogen, though oxygen, nitrogen, sulphur, and other minerals in varying proportions are also found in them. Some

bituminous substances contain oxygenated bodies and paraffins that crystallize at low temperatures. As all bituminous materials contain carbon and hydrogen they are classed in the hydrocarbon group of organic compounds.

Most bituminous substances range in color from white through various shades of yellow and brown to jet black, though some possess a greenish or reddish cast. Pure mineral wax is white, and asphalts are generally dark brown, grayish black, or jet-black. At 77° F. the specific gravity of bituminous material ranges from 0.75 to 1.75. The consistency depends upon the metamorphic stage and ranges from liquid through various degrees of viscosity to brittle. Petroleum is a liquid, native asphalt is variable, the asphaltites and asphaltic pyrobitumens are relatively hard; and mineral wax varies from viscous to solid. Crude petroleum has a characteristic oily odor.

The following table[1] shows the physical and chemical properties of bituminous substances:

[1] Abraham, Herbert, Asphalts and allied substances, p. 22, New York, D. Van Nostrand Co., 1918.

Properties of bituminous substances.

Bituminous substances.	Origin.	Physical properties.							Solubility.		Composition.
		Color in mass.	Consistency.	Luster.	Feel.	Odor.	Volatility.	Fusibility, nonmineral constituents.	Nonmineral constituents in carbon disulphide.	Sulphonation residue of 300° to 350° C. distillate.	
Bitumen	Native	Variable (light to dark).	Variable (liquid to solid).				Variable	Harder varieties are fusible.	Largely soluble.	Considerable	Hydrocarbons, substantially free from oxygenated bodies, sometimes associated with mineral matter.
Pyrobitumen	do	Dark	Comparatively hard.	Resinous to dull.	Nonadherent		Nonvolatile	Infusible	Relatively insoluble.		Hydrocarbons which may or may not contain oxygenated bodies, sometimes associated with mineral matter.
Petroleum	do	Variable (light to dark).	Liquid		Oily	Characteristic ("oily").	Comparatively volatile.		Soluble	Considerable	Hydrocarbons, substantially free from oxygenated bodies.
Mineral wax	Native or pyrogenous.	do	Viscous to solid.	Characteristic ("waxy")	Unctuous		Comparatively nonvolatile.	Fusible	do	do	Hydrocarbons, substantially free from oxygenated bodies, containing considerable crystallizable paraffins, sometimes associated with mineral matter.
Asphalt	do	Dark	Variable	Harder varities resinous. to dull.	Adherent to nonadherent.		do	do	Largely soluble.	do	Hydrocarbons, substantially free from oxygenated bodies, containing little to no crystallizable paraffins, sometimes associated with mineral matter.
Asphaltite	Native	do	Comparatively hard.	Resinous	Nonadherent.		Nonvolatile	Difficultly fusible	do	do	Hydrocarbons, substantially free from oxygenated bodies and crystallizable paraffins, sometimes associated with mineral matter.

USES.

WAR-TIME USES AND POSSIBILITIES.

A review of conditions in the asphalt and allied industries during the year in which the great World War terminated seems a fitting place wherein to discuss briefly the domestic sources of supply, the war-time uses and possibilities of asphalt and related bitumens, and the relation those commodities bear to a warring nation. The bitumens and pyrobitumens are used in the construction of pavements and in the manufacture of roofing, of other building material, and of rubber, products which are of great importance in time of war. Many new asphalt pavements were laid in this country in 1918 at cantonments, shipyards, and elsewhere in war work, and much asphaltic material was used in the manufacture of roofing for the thousands of temporary buildings that were erected in that year.

The domestic supply of asphalt and related bitumens is for all practical purposes unlimited; the large deposits of native asphalt have been scarcely touched; and the petroleum reserves contain an immense quantity of asphaltic material that can be obtained in the distillation process.

Petroleum refineries equipped for the manufacture of asphalt are located in practically all parts of the United States as follows:

Atlantic border:
Bayonne, N. J.; Philadelphia, Pa.; Baltimore, Md.
Interior:
Cleveland, Ohio; Lawrenceville, Ill.; Whiting, Ind.; Wood River, Ill.; Sugar Creek, Mo.; Independence, Kans.; Shreveport, La.
Gulf coast:
Destrehan and Baton Rouge, La.; and Beaumont, Port Arthur, and Texas City, Tex.
Pacific coast:
San Francisco, Bakersfield, Los Angeles, and Vernon, Calif.

The capacity of the refineries in any one of these districts is ample to care for all the asphalt requirements of the adjacent consuming territory provided the necessary supply of asphaltic oil is available.

In general paving cements now manufactured by the leading producers of petroleum asphalt are satisfactory and have in their favor the fact that the process of their manufacture yields valuable by-products—gasoline, kerosene, lubricants, and fuel oils—to the extent of approximately 50 per cent of the crude oil utilized. It must be acknowledged, however, that practically all oil asphalt manufactured in the country from Illinois, Oklahoma, Gulf coast, and Mexican petroleum is produced at the expense of fuel oil, a war necessity of equal, if not greater, importance than asphalt. It seems therefore that this country is independent of foreign asphalt, and that in case of need shipping engaged in the importation of native asphalt could be diverted to other purposes, as it was in a measure during the recent war.

The most important use of ozokerite is as acid-proof coating or backing for electrotypers' plates. Prior to the war the entire supply utilized in this country was imported chiefly from Galicia. When the foreign source of supply was cut off, a deposit near Soldier Sum-

mit, Wasatch County, Utah, was opened, and it has produced continuously since that time. The occurrence of the Utah ozokerite as irregular and nonpersistent deposits in fissures and brecciated zones and as thin films along joint planes in little-disturbed rocks permits no quantitative estimate of the underground reserves of this mineral in the area of its principal occurrence. Many prospects and mines, at present undeveloped, have disclosed ozokerite in various places, and it is probable that production could be materially increased if the operators were assured that the present high prices for ozokerite would remain in effect for several years.

ASPHALT AS PAVING MATERIAL.

Asphalt is most largely used in this country in paving city streets and country roads. Both petroleum and native asphalts are well adapted for this purpose. Paving cement, binder, filler, road oil, and flux are obtained as a residuum in the distillation of semi-asphaltic and asphaltic petroleum. Paving cement and binder are used in the construction of asphalt pavements, filler in the manufacture of asphalt blocks, road oil to allay dust, and flux in the treatment of native asphalt. Asphalt binder is also often used in the preparation of fuel briquets. Substantially the same products are obtained from native asphalt. If properly laid and maintained, asphalt pavements are durable, clean, give rise to relatively little noise and dust, and are universally popular for both city streets and rural highways. Typical standard specifications for bituminous road materials are given in United States Department of Agriculture Bulletin 691.

Bituminous rock, a variety of native asphalt, is used in the construction of city streets and country highways. Most of the pavements in the United States have heretofore been made with imported native asphalt and petroleum asphalt, but this country contains vast quantities of bituminous rock that could be economically used for paving, and this would release a large quantity of oil suitable for fuel. European countries use large amounts of bituminous rock in road construction, and many good pavements have been made with it in the United States.

The following data, explaining the use of bituminous rock in road construction, were contributed in substance by James S. Downard, of Sulphur, Okla.:

There are two methods of using bituminous rock in paving. According to one the rock is powdered, heated, spread about 2 inches thick upon a concrete foundation, and compressed by a steam roller. According to the other the bituminous rock is crushed and utilized in macadamizing.

The advantages of a bituminous-rock pavement are based upon its origin and composition. It is a limestone or sandstone saturated by nature with asphalt, the temper of which is of secondary importance in pavement construction. Properly constructed, bituminous-rock pavements contain a high percentage of filler and no excess asphalt and therefore are attractive, permanent, and waterproof and do not roll or creep.

Although good bituminous-rock pavements have been laid in Kansas City, Kans., Oklahoma City, Okla., and other cities, many rock-asphalt pavements constructed in the United States have been experimental and have not been successful because of the failure of the contractor to understand the nature of rock asphalt. Bituminous rock varies in quality, and each deposit must be analyzed and treated individually. One of the best known specifications is a mixture of 40 per cent bituminous limestone and 60 per cent bituminous sandstone. One-half of the bituminous sandstone should be ground finely and the remainder coarsely. Bituminous rock pavements are used in Kansas City, Kans.; Salt Lake City, Utah; San Francisco, Calif.; Ardmore, Ada, Norman, Houldenville, Pawhuska, Durant, Lawton, and Oklahoma City, Okla.; and Dallas, Bonham, Paris, Sherman, Mount Pleasant, San Antonio, Houston, and Beaumont, Tex. Some bituminous-rock pavements in Kansas City have been continuously and successfully used by heavy traffic for 20 years.

Two of the best bituminous-rock deposits in the United States for paving are in Murray County, Okla., and Uvalde County, Tex.

BITUMINOUS SUBSTANCES AS BUILDING MATERIAL.

The uses of bituminous substances, including both asphalt made from petroleum and native asphalt, as well as gilsonite, grahamite, and wurtzilite in buildings and other structures are manifold. Both viscous and liquid asphaltic products obtained from petroleum and crude native asphalt are used in the manufacture of asphaltic paints and in the treatment of felts and other fabrics for building material. Gilsonite is used in the manufacture of paint, japans, varnish, waterproofing, and insulation. Refined wurtzilite is utilized principally in the manufacture of insulation, marine and iron paints, acid-resisting compounds, and other protective coatings. The demand for wurtzilite, though small, appears to be increasing in consequence of its employment as a primary constituent of prepared flooring. In 1918 the use of grahamite in this country was restricted to roofing, but it is also suitable for the production of flooring, of varnish, and of filler for brick and stone blocks. Although these products have been marketed for relatively few years in the United States, as they are elastic, antiseptic, acid-resistant, and moisture-proof, they are in general demand among contractors and engineers, and their use is increasing.

OTHER USES.

Gilsonite has found great favor in the rubber industry. As pure rubber is sensitive to heat and cold it can not be used advantageously for making products that are exposed to extreme temperatures, but when it is mixed with gilsonite and the mixture is vulcanized the rubber undergoes changes in composition that enable it to resist variations in temperature as well as oxidation. The product of this mixture, which is called mineral rubber, is well adapted for the manufacture of rubber tires and for general outdoor use, and the demand for it is increasing.

Ozokerite is utilized in the manufacture of leather polish, sealing wax, electrotypers' wax, candles, electric insulation, carbon paper,

and ink. Most of the output in 1918 was used as an acid-proof coating for electrotypers' plates.

Ichthyol, though not produced in the United States, is imported and used by physicians as an alterative and discutient in treating certain skin diseases. It is a brown sirupy liquid produced by the dry distillation of bituminous material containing fossil fish. True ichthyol is said to be produced only from Austrian bitumen, but it is reported that since imports from Austria were cut off by the war equally effective substitutes have been discovered.

ASPHALT INDUSTRY IN FOREIGN COUNTRIES.

NORTH AMERICA.

CANADA.

Although there are large deposits of bituminous sandstone in northern Alberta, little has been done to develop them commercially. In 1913 a brief reconnaissance of the deposits was made by S. C. Ells, of the Canada Department of Mines, and in 1914 experimental pavements were constructed in Edmonton with material from these beds. After a year's use the pavement was in good condition, and therefore it seems that the material is well suited for highway paving. However, experimental work was discontinued in 1917 because of the entrance of Mr. Ells into the military service, and so far as can be ascertained it was not resumed in 1918.

MEXICO.

As shown by the following tables, increasing quantities of petroleum, largely of asphaltic base, are produced annually in Mexico and exported to the United States for the manufacture of petroleum asphalt and other products:

Petroleum produced in Mexico, 1901–1918.

	Barrels.		Barrels.
1901	10,345	1910	3,634,080
1902	40,200	1911	12,552,798

1914	879	19,491			

TRINIDAD.

For many years the island of Trinidad has been the chief contributor to the world's supply of native asphalt. The crude material is excavated from the famous pitch lake at the south end of the

island by the New Trinidad Lake Asphalt Co. (Ltd.), a subsidiary of the General Asphalt Co., and although large quantities of asphalt have been taken from the deposit the excavations are soon filled with fresh material and the quantity of asphalt available seems unlimited. The deposit is approximately 120 acres in extent and of unknown depth, the deepest test that has ever been made—150 feet—having failed to reach the bottom. The shifting of underlying strata in the lake bends or breaks drilling tools driven into them. Specimens of asphalt taken at various depths indicate that the deposit is of uniform composition.

The raw material is exported to both the United States and Europe, and streets paved with Trinidad asphalt are found throughout the world, the most famous being Pennsylvania Avenue, Washington, D. C.; the Thames-Victoria Embankment, London, England; and the Avenue de Paris, leading from Paris to Versailles, France. Most of the asphalt exported to the United States is refined by the Barber Asphalt Paving Co. at its plant in Maurer, N. J. It is apparent from the following tables that exports of asphalt from Trinidad declined materially in recent years, but as this was due to the situation brought about by the war, it would seem that the resumption of normal conditions should restore this trade to its prewar proportions.

Native asphalt produced in Trinidad, 1906–1918.[a]

TURKEY.

Although bitumen from the Dead Sea region in Palestine was probably used by the Assyrians and Babylonians in the construction of their palaces the deposits have not been used commercially for centuries. Bituminous cements have been identified in the ancient walls of the temple of Babylon, and there are ancient cisterns in Syria lined with bitumen that are still water-tight. The bituminous material in the Dead Sea region is said to be well adapted for road construction, and if it could be produced and used on the roads in the Near East, where because of climatic conditions and the narrow wheels of vehicles the highway problem is difficult to solve, transportation facilities could be improved.

STREET AND ALLEY PAVING IN THE UNITED STATES.

The following statistics collected by Engineering and Contracting [1] show the status of street and alley improvement in 185 typical municipalities in the United States in 1918 and "indicate that American cities have much work to do before they have a 100 per cent paved street mileage":

Paved and unpaved streets in 185 cities in the United States in 1918.

PRODUCERS.

The following operators reported to the United States Geological Survey that they produced asphaltic material from crude petroleum in the United States in 1918:

Asphaltum & Oil Refining Co., Los Angeles, Calif.
Atlantic Refining Co., 3144 Passyunk Avenue, Philadelphia, Pa.
California Fresno Oil Co., Fresno, Calif.
California Oil & Asphalt Co., 304–307 Grosse Building, Los Angeles, Calif.
Central Refining Co., Lawrenceville, Ill.
Craig Oil Co., Toledo, Ohio.
Fairchild-Gilmore-Wilton Co., 396 Pacific Electric Building, Los Angeles, Calif.
Freeport & Mexican Fuel Oil Corporation, 120 Broadway, New York, N. Y.
Gulf Refining Co., Frick Building Annex, Pittsburgh, Pa.
Hercules Oil Refining Co., 396 Pacific Building, Los Angeles, Calif.
Indian Refining Co., 44 Whitehall Street, New York, N. Y.
King Refining Co., 275 Holbrook Building, San Francisco, Calif.
Magnolia Petroleum Co., Box 1667, Dallas, Tex.
Paraffine Co. (Inc.), Emeryville, Calif.
Pierce Oil Corporation, 25 Broad Street, New York, N. Y.
Pine Island Refining Co., Shreveport, La.
Pioneer Asphalt Co., Lawrenceville, Ill.
Pioneer Paper Co., 251 South Los Angeles Street, Los Angeles, Calif.
Producers Refining Co., Bakersfield, Calif.
Prudential Oil Corporation, 17 Battery Place, New York, N. Y.
Seaside Oil Co., Summerland, Calif.
Shell Co. of California, Security Building, San Francisco, Calif.
Standard Asphalt & Refining Co., 208 La Salle Street, Chicago, Ill.
Standard Oil Co. of California, 200 Bush Street, San Francisco, Calif.
Standard Oil Co. of Indiana, 910 South Michigan Avenue, Chicago, Ill.

Standard Oil Co. of Louisiana, Baton Rouge, La.
Standard Oil Co. of New Jersey, 26 Broadway, New York, N. Y.
Texas Co., Houston, Tex.
Turner Oil Co., 1006 California Building, Los Angeles, Calif.
Union Oil Co. of California, 287 Mills Building, San Francisco, Calif.
United States Asphalt Refining Co., 90 West Street, New York, N. Y.
Warner Quinlan Asphalt Co., 79 Wall Street, New York, N. Y.

Native asphalt and related bitumens were produced commercially in this country in 1918 by the following companies:

American Asphalt Association, 918 Wainwright Building, St. Louis, Mo.
American Chemical & Ozokerite Co., 208 Kearns Building, Salt Lake City, Utah.
City Street Improvement Co., Seventeenth and Harrison streets, San Francisco, Calif.
Consolidated Bituminous Rock Co., 511 Nevada Building, San Francisco, Calif.
Fort Smith Asphalt Co., Fort Smith, Ark.
Gilson Asphaltum Co., 1900 Land Title Building, Philadelphia, Pa.
Kentucky Rock Asphalt Co., 712 Paul Jones Building, Louisville, Ky.
Raven Mining Co., Marquette Building, Chicago, Ill.
Sattler & Stevens, Carpinteria, Calif.
Uvalde Rock Asphalt Co., San Antonio, Tex.

SELECTED BIBLIOGRAPHY.

All the publications on petroleum and most of those on asphalt and related bitumens in the following bibliography were issued by the United States Geological Survey. The bulletins and the reports entitled "Mineral Resources of the United States" that are in stock may be obtained free by applying to the Director, United States Geological Survey, Washington, D. C. The folios of the Geologic Atlas are sold by the Survey, and many of the other reports that are no longer available for free distribution may be purchased from the Superintendent of Documents, Government Printing Office, Washington, D. C. Most of the publications in this list may be consulted in the public libraries of the larger cities.

PETROLEUM.[1]

ADAMS, G. I., Oil and gas fields of the western interior and northern Texas coal measures and of the upper Cretaceous and Tertiary of the western Gulf coast: Bull. 184, 64 pp., 1901.

MINERAL WATERS.

By Arthur J. Ellis.

SCOPE OF REPORT.

The term mineral water as it is used in this report applies to water that is bottled and sold in its natural state or only slightly altered from its natural state. It includes (*a*) natural carbonated waters that have lost part of their carbon dioxide; (*b*) natural waters that have been artificially carbonated; and (*c*) waters from which iron has been removed. It does not include artificial waters or natural waters that have been essentially modified in chemical character. Waters that have been flavored, concentrated, fortified, diluted, or otherwise radically altered are therefore not included.

The statistics in this report refer only to domestic mineral waters that have been sold, imports being excepted. Water that is given away, including water furnished free for drinking or bathing to guests at hotels or to patients at sanitariums, has been omitted even where there are data available to show the quantity of water so used. Hence, as actual sales fall far short of the total quantity used, particularly of such waters as are drunk at fashionable resorts for their medicinal value, the totals do not represent the full magnitude of the trade.

Three uses of mineral waters are recognized in this report—table use, medicinal use, and use in the manufacture of soft drinks.

Distinction for statistical purposes between table and medicinal waters is entirely arbitrary. Most table waters are clear, sparkling, and without distinct mineral taste or odor. Some table waters are, however, more strongly mineralized than some medicinal waters, and many medicinal waters contain less mineral matter than certain city supplies. The distinction in this report between table waters and medicinal waters is based on the reports furnished by the owners and operators of springs, which state the uses for which the waters are sold. An operator's report is, in turn, based on his knowledge of the uses to which his customers put the water. The reports show that as many as 90 waters are sold in the United States for both table and medicinal purposes, and that 29 waters are sold for table use, medicinal use, and use in the manufacture of soft drinks. It is apparent, therefore, that although this classification is useful for statistical purposes, it does not correspond to fundamental differences in composition in the waters themselves.

USES OF MINERAL WATERS.

The figures in the following table are grouped according to uses of the water. As shown in this table 90 waters are sold for both medicinal and table use and might properly be classed as table waters. These, together with the 323 waters that are sold exclusively for table use, make in all 413 table waters, as compared with 140 waters sold exclusively for medicinal use.

Number of springs supplying water of each class in 1918.

State.	Number of mineral waters.[a]	Sold for table use only.	Sold for medicinal use only.	Sold for both table and medicinal uses.	Used for soft drinks.	Used for soft drinks only.	Used for soft drinks and sold for table purposes.	Used for soft drinks and sold for medicinal purposes.	Used for soft drinks and sold for table and medicinal purposes.

[a] Equivalent to the number of active springs.

MAP OF THE

UNITED STATES

SHOWING DISTRIBUTION OF SOURCES OF
MINERAL WATERS SOLD IN 1918

For exact location of wells see table for each State in text

SOURCES OF MINERAL WATERS.

The mineral waters sold in the United States are for the most part derived from natural springs. Many, however, are obtained from wells, and some from streams. No distinction is made in this report between mineral water flowing or pumped from a natural spring and that flowing or pumped from a dug, bored, driven, or drilled well, but wherever the available information permits the sources are given their proper designations in the tables as springs or wells.

The geographic distribution of the sources of mineral waters sold in the United States in 1918 is shown on Plate V. The springs and wells, the operators of which cooperate with the Geological Survey by furnishing reports on the volume of business, are shown as accurately as possible.

MINERAL-WATER TRADE IN 1918.

OUTPUT AND VALUE.

The number of mineral springs utilized commercially was smaller in 1918 than in 1917, as were also the quantity and value of the water sold from them.

Wisconsin ranked first and New York second in quantity and value of mineral waters sold for all purposes and were followed in order by California, Maine, Indiana, and Virginia. Massachusetts ranked first in the consumption of mineral waters for soft drinks; Indiana was first in value of medicinal waters, and California and New York were in second and third place, respectively. In value of table waters, Wisconsin, in first place, and New York, in second place, were followed in order by California, Maine, Ohio, Michigan, Virginia, and Massachusetts. More than 25 springs were active in each of 8 States, more than 1,000,000 gallons of mineral water was sold in each of 13 States, and the value of the water sold amounted to more than $100,000 in each of 12 States.

Sales were reported from 569 springs in 1918, as compared with 717 springs in 1917. No reports of mineral-water sales were received from Arizona, Idaho, or Utah, and less than three commercially productive springs each were reported from Delaware, District of Columbia, Louisiana, Nevada, New Mexico, and Washington; three or more springs were productive in every other State in the Union. Sales exceeded 5,000,000 gallons in New York and Wisconsin, and the total value of the product was more than $1,000,000 in Wisconsin and more than $500,000 in New York.

As shown in the following table, 90 per cent of all the mineral waters sold in the United States in 1918 came from 21 States. All other States than those mentioned in the following table furnished less than 1 per cent each.

Not all of this water was consumed in the United States, a considerable quantity being exported, but no separate statistics of exports are available.

CONDITION OF TRADE.

The total quantity of mineral waters sold in 1918 was less than in any year since 1903 and the total value was less than in any year since 1896. The decrease in sales of mineral waters during the war period is shown in the following table:

Mineral waters sold in the United States, 1913–1918.

Year.	Commercial springs.	Quantity. sold.	Value.	Average price per gallon.
		Gallons.		*Cents.*

b Includes in 1917 Delaware, District of Columbia, Nebraska, and Nevada; in 1918 ,Delaware, District of Columbia, Louisiana, Nevada New Mexico, and Washington.

RANGE OF PRICE.

Effort has been made in compiling the following table, which gives the quantity and value of mineral water sold within certain ranges of price during 1917 and 1918, to eliminate freight and marketing charges and the value of returnable containers, and thus to give the net value of the waters at their sources.

Range of price per gallon of mineral water, 1917 and 1918.

Price per gallon (in cents).	Number of springs.	Quantity sold.	Value.	Percentage of number of springs.	Percentage of total quantity.	Percentage of total value.

[a] Exclusive of 20 springs whose waters are used exclusively in the manufacture of soft drinks.
[b] Exclusive of 16 springs whose waters are used exclusively in the manufacture of soft drinks.

Practically four-fifths of the mineral waters was sold at prices ranging from half a cent to 10 cents a gallon during 1913, 1914, 1915, 1916, 1917, and 1918. The percentage sold for more than 30 cents a gallon was 9.7 per cent in 1918, as compared with 10 per cent in 1917. The water from 357 springs was sold for 10 cents or less a gallon, and the water from 8 springs was sold for more than $1 a gallon. The average price per gallon in 1918 was 11 cents.

SOFT DRINKS.

Returns show that the quantity of mineral water used in the manufacture of soft drinks in 1918 was more than in 1917. The gross distribution of the consumption during 1918 is indicated in the following table. Massachusetts heads the list with a consumption greater than 1,800,000 gallons and Wisconsin follows with nearly 1,500,000 gallons. In addition to Massachusetts and Wisconsin 12 States reported consumption exceeding 100,000 gallons each, and 17 other States reported a combined consumption of 705,837 gallons. This recorded consumption does not represent the total production of soft drinks in the United States, as most of them are compounded with municipal and private supplies not classified as mineral waters.

Mineral waters used in the manufacture of soft drinks in 1918.

Rank.	State.	Quantity.	Rank.	State.	Quantity.
		Gallons.			*Gallons.*
1	Massachusetts	1,819,246	10	Iowa	215,000

5	New Hamppshire	377,403	14	Maryland	119,642
6	South Carolina	300,000		Other States	705,837
7	Connecticut	278,663			
8	Minnesota	278,651			7,220,944
9	New York	250,478			

EXPORTS.

Large quantities of a few domestic waters are exported, but no statistics regarding such shipments are available. The quantity and the value of these waters are included in the statistics of production for the United States.

IMPORTS.

Until July 1, 1918, the statistics of imports of mineral waters, as reported by the Bureau of Foreign and Domestic Commerce, Department of Commerce, included artificial mineral waters and imitations of natural mineral waters. Figures relative exclusively to the imports of natural waters were not available. After July 1, 1918, records were kept of the imports of natural waters, and these are available for this report. Owing to this change in the records it is not practicable to make a direct comparison between the figures for the last half of 1918 and those for the first half and for preceding years.

The total imports of natural and artificial mineral waters entered for consumption in the period January to June, inclusive, 1918, amounted to 288,701 gallons, valued at points of shipment at $138,671 or an average of 48 cents a gallon. From July to December, inclusive, 1918, the imports for consumption of natural mineral waters exclusively amounted to 200,786 gallons, valued at points of shipment at $102,970, the average price per gallon being 51 cents. During the entire year 1918 there was imported for consumption in this country, 3,566,346 pounds of mineral salts, obtained by evaporation from natural mineral waters. These imports were valued at $10,231.

Mineral waters imported for consumption in the United States, 1914–1918.

Year.	Quantity.	Value.	Price per gallon.
	Gallons.		*Cents.*
1914	2,786,142	$857,707	31
1915	1,528,181	551,648	36
1916	1,553,199	624,302	40
1917	618,405	268,665	43
1918 January to June	288,701	138,671	48
1918 July to December[a]	200,786	102,970	51

[a] Natural mineral waters exclusively. Figures for first half of 1918 and for all preceding years, include artificial mineral waters and imitation mineral waters, in addition to natural mineral waters.

The following table shows the general imports by principal countries. The figures include both artificial mineral waters and imitations of minerals waters.

Mineral waters imported into the United States, by countries, in 1918.

Country.	Quantity (gallons).	Value.	Country.	Quantity (gallons).	Value.
France	560,058	$240,212	Mexico	9	$3
Italy	675	394	Cuba	99	42
Spain	2,970	1,445	Japan	2,661	460
England	18	9	Australia	12	15
Ireland	12	9			
Canada	366	165		566,880	242,754

"General imports" and "imports for consumption" for any period will differ to the extent that the value of entries for warehouse for the period differs from the value of withdrawals from warehouse for consumption. The term "entry for consumption" is the technical name of the import entry made at the customhouse and implies that the goods have been delivered into the custody of the importer and that the duties have been paid on the dutiable portion.

MINERAL-WATER TRADE BY STATES.[1]

ALABAMA.

Returns from Alabama indicate that the mineral-water trade in 1918 was about 89 per cent less than it was in 1917. The sales amounted to 6,315 gallons, and the value of the output was $1,808, the average price per gallon increasing from 10 cents to 29 cents. There was a considerable decrease in the value of the output of table waters, from $2,072 to $120. Three springs which were active in 1917 reported no sales for 1918; three from which no reports were received were omitted; and one which was idle in 1917 reported sales in 1918. Three resorts accommodating about 185 guests were maintained. No bathing establishments were maintained and no mineral waters were used in the manufacture of soft drinks.

ARKANSAS.

The sales of mineral waters in Arkansas during 1918 were 863,142 gallons, as reported from eight active springs, a decrease of more than 15 per cent from the output in 1917. The average price of the water remained the same, 8 cents, and the total value of the output amounted to $70,626, which was about 10 per cent less than the total value of sales in 1917. The sales of table waters showed a large falling off, from $16,399 to $8,595, and the sales of medicinal waters increased slightly.

One spring which was active in 1917 reported no sales in 1918; from two which reported in 1917 no figures were obtainable in 1918; two springs which reported no sales in 1917 were active in 1918; and one spring which did not report in 1917 reported sales in 1918.

About 62 guests, exclusive of Eureka (Springs) and Hot Springs, were accommodated, in addition to which 100,000 gallons of mineral water was used in the manufacture of soft drinks, as compared with 250,000 gallons used for this purpose in 1917.

CALIFORNIA.

The output of mineral waters in California in 1918 showed a decrease of about 7 per cent in quantity and 5 per cent in value, as compared with the output in 1917.

The total quantity sold was 2,399,144 gallons. Medicinal waters sold for $140,808 and table waters for $292,202—a total of $433,010, the average price being 18 cents.

The output of one spring from which no report could be obtained has been estimated. The number of active springs was 38. Mineral-water baths were maintained at 13 springs, and 12 resorts, accommodating about 3,000 guests, were operated. In the manufacture of soft drinks, 146,875 gallons of mineral water was used.

COLORADO.

There has been since 1911 a decrease each year in the quantity of mineral waters sold in Colorado. There was a decrease of 28 per cent in quantity in 1918, but an increase of 25 per cent in value, compared with decreases of 18 per cent in quantity and 46 per cent in value, in 1917. There was an increase of 10 cents in the average price received for the water, the price being 25 cents in 1918. The sales of medicinal waters increased from $25,679 in 1917 to $34,284 in 1918, and the sales of table waters from $39,490 in 1917 to $47,083 in 1918.

Reports were received from 11 active springs. Four bathing establishments were maintained—the same number as in 1917—and 3 resorts, accommodating about 1,700 guests. In the manufacture of soft drinks 176,831 gallons of water was used. Lithia Springs are now called Pueblo Mineral Springs.

CONNECTICUT.

The output of mineral waters in Connecticut decreased 31 per cent in quantity and 30 per cent in value in 1918, the average price remaining the same, 5 cents. In 1917 a decrease in the sales of table waters and a 63 per cent increase in the sales of medicinal waters were reported. The returns for 1918 show a very decided increase in the value of medicinal waters—from $3,127 in 1917 to $12,073—and a decrease—from $100,851 in 1917 to $60,454 in 1918—in the value of table waters sold. The total value of sales in 1918 was $72,527.

Del-Vale Spring, situated near Canton, reported for the first time. Twenty-seven active springs reported, or four less than in 1917. No resorts or mineral-water baths were reported. About 278,663 gallons of mineral waters was used in the manufacture of soft drinks, a decrease of 31,197 gallons from the quantity used in 1917.

DELAWARE.

Reports have been received from only one spring in Delaware during the last eight years, the water being used chiefly on the table by residents of Wilmington. The spring is called Kiamensi Springs near Wilmington, Newcastle County.

DISTRICT OF COLUMBIA.

One spring in the District of Columbia reported sales during 1918, namely, Red Oak Spring, near Langdon.

FLORIDA.

Returns from Florida showed an increase of 16 per cent in quantity and 31 per cent in value of mineral waters sold in 1918, as compared with 1917. Five springs were active in 1918. One spring idle in 1917 produced in 1918 and two springs active in 1917 reported no sales for 1918. Another spring from which no report was received was considered idle.

The total output was 164,630 gallons, valued at $12,883. The average price per gallon decreased from 7 cents to 6 cents.

Two bathing establishments and two resorts, accommodating 30 persons, were maintained.

GEORGIA.

The sales of mineral waters in Georgia decreased 24 per cent in quantity and 26 per cent in value in 1918, and the price per gallon remained about the same, 9 cents. The sales were 314,388 gallons, valued at $27,810. One bathing establishment and two resorts, accommodating 550 guests, were maintained at springs. Two springs active in 1917 were idle in 1918; one spring from which no report was received has been considered idle; and one spring from which no report was received in 1917 was active in 1918. Crystal Mineral Spring reported sales for the first time.

ILLINOIS.

The sales of mineral waters in Illinois decreased 33 per cent in quantity and 34 per cent in value in 1918. The total sales were 921,953 gallons, valued at $43,448, of which $1,337 was received for medicinal waters and $42,111 for table waters. Three springs active in 1917 reported no sales for 1918, and one from which no report was received was estimated.

The quantity of mineral waters used in the manufacture of soft drinks decreased from 44,043 to 32,668 gallons. Resorts for about 400 guests were maintained at 4 springs, and mineral-water bathing establishments were maintained at 6 springs.

INDIANA.

Indiana sold 555,076 gallons of mineral waters in 1918—6 per cent more than in 1917—valued at $179,431. The average price per gallon increased from 29 to 32 cents. There was an increase in the sales of both medicinal and table waters. Five springs active in 1917 reported no sales in 1918. Five bathing establishments and four resorts, accommodating 900 guests, were maintained.

IOWA.

The reported output of mineral waters in Iowa during 1918 was 87,703 gallons, sold for $3,937, as compared with 99,103 gallons, sold for $12,125, in 1917. These figures correspond to a decrease in quantity and value, respectively, of 12 per cent and 68 per cent. The average price per gallon decreased from 12 to 4 cents. One spring which was active in 1917 was not heard from in 1918 and has been considered idle. Lime Rock Spring is added to the list for the first time. More than 200,000 gallons of mineral waters was used in the manufacture of soft drinks. No mineral-water bathing establishments nor resorts were maintained.

KANSAS.

The mineral-water business in Kansas showed an increase in 1918 in both quantity and value. The total sales amounted to 403,862 gallons, or 40 per cent more than in 1917, valued at $75,359, or 11 per cent more than in 1917. The average price per gallon dropped from 23 to 19 cents. One spring active in 1917 reported no sales in 1918. Two mineral-water bathing establishments accommodated 70 guests at two resorts. Fifteen thousand gallons of mineral waters was used in the manufacture of soft drinks.

KENTUCKY.

The reports for 1918 show a decline in the quantity of mineral water sold in Kentucky. There was a decrease of 15 per cent in quantity but an increase of 4 per cent in value. The sales reported in

1918 amounted to 255,852 gallons, as compared with 301,748 gallons in 1917, and the value of the output was $41,997, as compared with $40,189 in 1917. The average price increased from 13 to 16 cents. Two springs which marketed water in 1917 reported no sales in 1918; two springs which were active in 1917 were not heard from in 1918; one spring idle in 1917 reported sales in 1918; and one new spring was added to the list; thus the total number of active springs was 11. Renfo Mineral Springs was added to the list for the first time.

Three resorts, accommodating 115 guests, exclusive of the capacity of Dawson Springs, and two mineral-water bathing establishments were maintained. In addition to this 65,520 gallons of mineral water was used in making soft drinks.

LOUISIANA.

Only one spring in Louisiana reported in 1918. The water was sold for medicinal purposes.

The spring is named Krotz Springs, Krotz Springs, St. Landry Parish.

MAINE.

The output of mineral water in Maine was 829,338 gallons, valued at $266,168; the number of active springs decreased from 24 to 21. The average price per gallon was 32 cents. One spring active in 1917 reported no sales in 1918; two springs from which no reports were received were omitted; and one spring from which no report was received was estimated.

The mineral water used in the manufacture of soft drinks was 70,196 gallons, a decrease of 16,307 gallons from the quantity used in 1917. One resort for guests was maintained, but no bathing establishments using mineral water were reported.

MARYLAND.

Reports for 1918 show an increase, as compared with 1917, of 5 per cent in quantity and 16 per cent in value of mineral water sold in Maryland. There had been a decline in 1917 of 21 per cent in quantity and 12 per cent in value. The total sales in 1918 amounted to 1,089,966 gallons, valued at $100,575. The output was almost entirely table water. Green Spring reported sales for the first time. In addition to the quantity reported sold, 119,642 gallons was used in the manufacture of soft drinks, as compared with 175,426 gallons in 1917. One resort for guests was maintained, but no bathing establishments using mineral water.

MASSACHUSETTS.

Returns from Massachusetts for 1918 indicate a decrease of 31 per cent in quantity and 10 per cent in value of mineral waters sold. The average price per gallon increased from 5 to 6 cents. The sales amounted to 1,999,592 gallons, valued at $125,208. In addition to the quantity reported as sold, 1,819,246 gallons was used in the manufacture of soft drinks, as compared with 893,926 gallons in 1917—an increase of 104 per cent. One spring active in 1917 reported no sales in 1918, and 3 springs active in 1917 were not heard from in 1918. Mount Vernon Spring is now called Cline Spring.

One small resort was maintained, and one mineral-water bathing establishment was reported.

MICHIGAN.

The total sales of mineral waters in Michigan in 1918 was 1,216,882 gallons, as compared with 1,069,164 gallons in 1917, an increase of 14 per cent; and the total value was $129,592, as compared with $105,641 for 1917. The sales of table waters amounted to $128,809, and medicinal waters netted only $783. Two springs active in 1917 were not heard from in 1918 and have been considered idle, and one spring active in 1917 reported no sales in 1918; thus the number of active springs decreased from 12 to 9. Two resorts accommodating 1,000 guests were maintained, but no bathing establishments were operated.

In addition to the mineral water sold about 31,200 gallons, as compared with 43,700 gallons in 1917, was used in the manufacture of soft drinks.

MINNESOTA.

According to reports received from 16 active springs in Minnesota, the sales of mineral waters in that State decreased 25 per cent in quantity and 10 per cent in value in 1918. The total output was 2,248,731 gallons, valued at $99,159. The sales of table water increased from $77,436 in 1917 to $98,976 in 1918, but the sales of medicinal waters decreased from $32,528 in 1917 to only $183 in 1918. The average price per gallon remained the same, 4 cents. All the springs that were active in 1917 reported sales in 1918 except one. One resort for guests and one mineral-water bathing establishment were operated at springs. In addition to the sales reported 278,651 gallons were used in the manufacture of soft drinks.

MISSISSIPPI.

The mineral-water business in Mississippi, which decreased notably in 1917, underwent a further decrease of 11 per cent in quantity and 5 per cent in value in 1918, the sales reported being 175,533 gallons, all classed as medicinal water, valued at $47,539, as compared with 197,555 gallons, valued at $49,786 in 1917. The price per gallon increased from 25 to 27 cents. Two springs active in 1917 reported no sales in 1918, and 3 springs which reported sales in 1917 and were not heard from in 1918 were considered idle. The report of one spring was estimated. One mineral-water bathing establishment and four resorts, accommodating about 1,000 guests, were maintained at springs.

MISSOURI.

The decrease in the sales of mineral waters in 1917 in Missouri was marked by a further decline in the output in 1918 of 24 per cent in quantity and 33 per cent in value. The total output for 1918 was 306,299 gallons, valued at $38,478. The average price per gallon decreased from 14 to 13 cents. In addition to the quantity reported as sold, 13,787 gallons was used in the manufacture of soft drinks, a decrease from the quantity reported for 1917 of 21,436 gallons, or 61 per cent. Reports for 1918 were received from 26 active springs, as compared with 33 in 1917. Three springs active in 1917 reported no sales in 1918, and four springs active in 1917 were not heard from in 1918 and were considered idle. Two resorts, exclusive of those at Excelsior Springs, and three mineral-water bathing establishments were operated.

MONTANA.

The sales from three springs reporting from Montana in 1918 were 193,557 gallons, valued at $8,912. This represents a loss in quantity in 1918 of 8 per cent and in value of 7 per cent. The same springs active in 1917 reported for 1918, with one exception.

Mineral-water bathing establishments were maintained at two of these springs, and one resort accommodating 100 guests was reported. Practically all the water was sold for table use.

NEVADA.

One spring reported sales of mineral waters in 1918 in Nevada, the entire output being sold for table use.

The spring is called the Diamond Spring, Reno, Washoe County.

NEW HAMPSHIRE.

Returns from New Hampshire indicate a substantial increase in both quantity and value of mineral water marketed in 1918. The total sales in 1918 were 182,326 gallons, as compared with 105,181 gallons in 1917, and the total value of the output was $8,256, as compared with $6,975 in 1917. All of the output was classified as table water. The average price per gallon decreased from 7 to 5 cents. Three springs that were active in 1917 reported no sales in 1918, and one spring which was not heard from was omitted. No new springs were reported. In addition to the mineral water sold, 377,403 gallons was used in the manufacture of soft drinks, as compared with 477,937 gallons in 1917.

NEW JERSEY.

The sale of mineral waters in New Jersey decreased from 1,283,157 gallons in 1917 to 1,134,848 gallons in 1918, a loss in quantity of nearly 12 per cent and in value from $115,188 to $110,150, or about 4 per cent. The average price per gallon was 10 cents. Most of the output was classified as table water. In addition to the water reported as sold, 47,264 gallons was used in the manufacture of soft drinks, as compared with 73,605 gallons used in that business in 1917 No new springs were reported; one spring which reported sales in 1917 failed to report for 1918; thus the number of active springs decreased from 14 to 13. One mineral-water bath was reported to have been maintained.

NEW MEXICO.

Reports of sales of mineral waters in New Mexico in 1918 were received from one well only, which is called Perry Well and is 15 miles southeast of Albuquerque.

NEW YORK.

The State of New York in 1918 ranked first in number of active mineral springs, second in total quantity of mineral waters sold, second in total value of sales and in value of table waters, third in value of medicinal waters, and ninth in consumption of mineral waters for the manufacture of soft drinks. Comparison of figures for 1918 with those of 1917 shows a decrease of 25 per cent in quantity and an increase of less than 1 per cent in value in 1918. Most of the water was sold for table use. In 1918 there were 50 active springs, as against 65 in 1917. An additional quantity of 250,478 gallons was used in the manufacture of soft drinks in 1918. Two resorts, besides those at Saratoga Springs, and three mineral-water bathing establishments were operated in 1918. Sun Ray Spring is now called Clysmic Spring, and the name of Monarch Spring has been changed to Taconic Spring.

NORTH CAROLINA.

The sales of mineral waters in North Carolina showed a decrease in 1918 of 37 per cent in quantity and 48 per cent in value. The average price per gallon decreased from 15 to 12 cents. The sales amounted to 65,422 gallons, valued at $8,174, as compared with 103,659 gallons, valued at $15,664, in 1917. Six springs active in 1917 reported no sales in 1918; three springs were not heard from; Rock Hill Spring reported for the first time; thus the number of active springs in 1918 decreased from 18 to 10. Four resorts, accommodating about 500 guests, and one establishment for bathing in mineral water were maintained at springs.

NORTH DAKOTA.

Reports of sales were received from three active springs in North Dakota—the same number as in 1917—which showed a decrease in sales of 5 per cent in quantity but an increase of 7 per cent in value. The total output was 530,000 gallons, valued at $13,700, as compared with 556,000 gallons, valued at $12,837, in 1917. In addition to the quantity reported as sold, 30,000 gallons was used in the manufacture of soft drinks, a very considerable decrease from 120,000 gallons, the quantity used in 1917.

OHIO.

Returns from Ohio in 1918 showed a decrease in the sales of mineral waters of 11 per cent in quantity but an increase of 10 per cent in value. The total output was 2,771,485 gallons, valued at $150,711, as compared with 3,113,093 gallons, valued at $136,710 in 1917. The average price per gallon, which has been 4 cents for the last eight years, rose to 5 cents. The mineral water used in the manufacture of soft drinks decreased from 248,000 gallons to 145,000 gallons. Seven springs active in 1917 reported no sales in 1918; thus the number of active springs in 1918 was reduced to 24. Three resorts, accommodating about 300 guests, and one mineral-water bathing establishment were maintained.

OKLAHOMA.

The output of mineral water in Oklahoma in 1918 was 1,166,485 gallons, valued at $20,249, as compared with 852,381 gallons, valued at $26,997 in 1917. These figures indicate an increase of 37 per cent in quantity and a decrease of 25 per cent in value. In addition to the quantity sold, 51,846 gallons of mineral water was consumed in the manufacture of soft drinks. One spring active in 1917 reported no sales in 1918; another from which no report was received was omitted. No bathing establishments or resorts were reported to have been maintained.

OREGON.

Returns for 1918 show a decrease of 1 per cent in quantity and 36 per cent in value of mineral waters sold in Oregon in 1918. The sales were 13,550 gallons, valued at $1,825, as compared with 13,741 gallons, valued at $2,842, in 1917. The average price per gallon declined from 21 to 13 cents. One spring which was active in 1917 and was not heard from in 1918 was omitted; thus the number of active springs was reduced from 5 to 4. Two resorts accommodating about 150 guests and three mineral-water bathing establishments were maintained. In addition to the water reported sold, 6,050 gallons was used in the manufacture of soft drinks, a decrease of 6,950 gallons from the amount used for this purpose in 1917.

PENNSYLVANIA.

The returns from Pennsylvania indicate a decrease of 13 per cent in quantity and 16 per cent in value of mineral water sold in 1918, as compared with 1917. The price per gallon remained about the same, 9 cents. The total output was 1,400,456 gallons, valued at $123,436. The sales of table water amounted to $112,540, and $10,896 was reported from sales of medicinal water. In addition, 463,832 gallons was used in the manufacture of soft drinks, an increase as compared with 1917.

Thirty springs were active in 1918, a decrease of 11. Four springs which marketed water in 1917 were inactive in 1918; six others which were not heard from were omitted; and the output of one spring was estimated. Five resorts accommodating 745 guests and two mineral water bathing establishments were maintained.

RHODE ISLAND.

Rhode Island in 1918 reported sales from six springs amounting to 365,705 gallons, valued at $30,729. The average price per gallon was 8 cents. The water was sold exclusively for table use, and in addition 37,833 gallons was used in the manufacture of soft drinks, as against 31,830 gallons used for this purpose in 1917. The sales in 1917, at 7 cents a gallon, amounted to 368,976 gallons, valued at $24,975. Thus there was a decrease of nearly 1 per cent in quantity and an increase of 23 per cent in value in 1918.

SOUTH CAROLINA.

The sales of mineral water in South Carolina during 1918 amounted to 279,300 gallons, valued at $51,198, as compared with 289,094 gallons, valued at $45,729, in 1917. These changes are equivalent to a decrease of 3 per cent in quantity and an increase of 12 per cent in value. Ninety-five per cent of the output was sold for medicinal use. One spring active in 1917 was idle in 1918; two springs idle in 1917 reported sales in 1918. One of these, Economy Spring, was formerly called White Diamond Lithia Spring. One resort accommodating 325 guests was maintained. In addition to the mineral water reported sold, 300,000 gallons was used in the manufacture of soft drinks.

SOUTH DAKOTA.

Three springs in South Dakota reported sales in 1918 which amounted to 454,865 gallons, valued at $17,269, as compared with 443,167 gallons, valued at $13,545, in 1917, an increase of 3 per cent in quantity and 27 per cent in value. The average price per gallon rose from 3 to 4 cents. All but 65 gallons of this water was sold for table use, and 11,875 gallons in addition was used in the manufacture of soft drinks. No resorts or bathing establishments were maintained.

TENNESSEE.

The mineral-water trade of Tennessee showed an increase in 1918 of 31 per cent in quantity and 13 per cent in value. The average price per gallon decreased for the first time in six years from 6 to 5 cents.

The total output for 1918 was 990,027 gallons, valued at $53,367, as compared with 758,193 gallons, valued at $47,362, in 1917. The sales of medicinal waters amounted to $10,413 and of table waters to $42,954. Six springs active in 1917 reported no sales in 1918; one unreported spring was omitted; and Gibson Wells reported sales for the first time. Thus the number of active springs in 1918 was reduced to 13. Seven resorts, accommodating about 1,300 guests, were operated.

TEXAS.

There was an increase in the sales of mineral waters in Texas in 1918 of about 0.6 per cent in quantity and 12 per cent in value, all of the water being reported as sold for medicinal use. The total sales amounted to 544,183 gallons, valued at $80,553. In addition, about 30,000 gallons of mineral water was consumed in the manufacture of soft drinks.

No new springs were reported. Six springs active in 1917 reported no sales for 1918; one spring idle in 1917 was active in 1918; and four springs active in 1917 were not heard from in 1918. Two resorts, accommodating about 300 guests, and one mineral-water bathing establishment were reported.

VERMONT.

The mineral-water trade in Vermont in 1918 was 1 per cent greater in quantity and 3 per cent less in value than in 1917. The total sales were 95,700 gallons, valued at $17,090, as compared with 94,500 gallons, valued at $17,705 in 1917. The average price per gallon fell from 19 to 18 cents. In addition to the mineral water reported sold, about 30,000 gallons was used in the manufacture of soft drinks. Two resorts, accommodating 600 guests, and one mineral-water bathing establishment were maintained. The same springs active in 1917 reported sales for 1918.

VIRGINIA.

Returns from Virginia show that in 1918 the sales of mineral waters in that State decreased 31 per cent in quantity and 27 per cent in value, largely on account of a decrease in the sales of medicinal water. The total output was 1,745,105 gallons, valued at $173,912, as compared with 2,518,050 gallons, valued at $237,788, in 1917. The average price rose from 9 to 10 cents per gallon. In addition to the water reported as sold 519,586 gallons was used in the manufacture of soft drinks.

Five springs active in 1917 reported no sales in 1918; three springs active in 1917 were not heard from in 1918; two springs idle in 1917 reported sales in 1918; and one spring reported sales for the first time. Ten resorts, accommodating about 1,700 guests, and four mineral-water bathing establishments were maintained at springs.

Craig Healing Springs, Craig County, is reported in the list of active springs for the first time.

WASHINGTON.

Reports of sales of mineral waters in Washington were received from one spring only. It is called the Artesian Mineral Well, North Yakima, Yakima County.

WEST VIRGINIA.

The output of mineral waters in West Virginia in 1918 amounted to 301,883 gallons, valued at $32,045, as compared with 156,267 gallons, valued at $37,529, in 1917. This change is equivalent to an increase of 93 per cent in quantity and a decrease of 15 per cent in value. One spring active in 1917 was not heard from in 1918; one spring active in 1917 reported no sales in 1918; two springs idle in 1917 reported sales in 1918; and one new spring was added to the list. Thus the number of active springs in 1918 was 8. Three resorts, accommodating 1,150 guests, and two mineral-water bathing establishments were operated at springs.

WISCONSIN.

The sales of mineral waters in Wisconsin increased in 1918. The total output was 6,630,725 gallons, valued at $1,193,345, as compared with 6,296,634 gallons, valued at $1,362,498, in 1917. These figures represent an increase of 5 per cent in quantity and a decrease of 12 per cent in value. The sales of table waters amounted to $1,153,608, and of medicinal waters to $39,737. The average price per gallon fell from 22 to 18 cents. In addition to the water reported as sold, 1,423,900 gallons was used in the manufacture of soft drinks. Wisconsin ranked first in total quantity and value of mineral waters sold in 1918, and second in consumption of mineral waters for the manufacture of soft drinks. One resort accommodating 1,200 guests was maintained, but no bathing establishment was operated at springs. One spring temporarily idle in 1917 was active in 1918; five springs active in 1917 reported no sales in 1918; thus the number of active springs in 1918 was 32, against 36 in 1917.

WYOMING.

Sales from 4 springs in Wyoming in 1918 amounted to 41,335 gallons, valued at $5,513, or a decrease in quantity of 23 per cent and in value of 30 per cent, as compared with the output in 1917. One small resort and two mineral-water bathing establishments were operated, and about 500 gallons of mineral water also was used in the manufacture of soft drinks.

ARCHITECTURAL CONCRETE STONE AND CONCRETE BLOCKS IN 1917 AND 1918.[1]

By G. F. Loughlin.

INTRODUCTION.

In 1917, having received numerous requests for statistical information on the production of artificial stone, the United States Geological Survey undertook to canvass the producers and to issue a report on artificial stone as a supplement to the regular annual reports on natural stone, cement, and sand and gravel. This work had to be carried on in odd moments, and owing to lack of office force and to the many pressing demands on the Survey for special war information, compilation of the figures for 1917 could not be completed until 1919. It was therefore decided to publish the reports for 1917 and 1918 together.

Preparation of the figures for 1918 has also been greatly retarded by pressure of work which had priority, by the extra work involved in the systematizing of data obtained for the first time, and by the need for sending repeated requests to producers who failed to reply. In 1917 requests were sent to 3,200 firms, of which only 1,295 made reply. Several of these firms reported that they were out of business. In 1918 requests were sent to 2,830 firms, and when replies were not received within a reasonable time, second and even third requests were sent. To one or another of these three requests 1,962 firms made reply, and the figures for 1918 are therefore much more accurate than those for 1917, especially as to concrete blocks and miscellaneous products. The figures for architectural concrete stone for the two years are believed, however, to be essentially accurate. According to the replies received, 609 firms were active in 1917 and 920 in 1918; of these, 62 firms in 1917 and 42 firms in 1918 reported sales of architectural concrete stone.

On the blanks sent to producers the term "artificial stone" was used, but inasmuch as the products represented are all ordinary or special concrete mixtures of Portland cement, with different aggregates, and as at least some of the producers are chartered under State laws as "concrete-stone manufacturers," their suggestion to replace the terms "artificial stone" by "concrete stone" has been adopted. Some producers, however, specifically advertise "artificial" or "imitation" stone.

The product of principal interest to architects and to the building industry in general is that which serves the same purpose as natural cut stone and terra cotta in the facings and trimmings of the larger and more elaborate buildings. This product is designated "architectural concrete stone." A few manufacturers reported the production of "Mycenian marble," "Scagliola," "staff," and other

[1] The statistics in this report were complied by Miss A. E. Davis, of the United States Geological Survey.

gypsum products; but as the quantity of these can be estimated from the combined domestic production and imports of Keene's cement, no effort was made to include them in this report. Most producers reported "concrete blocks" or "concrete bricks"—products used principally for foundations and for facings and trimmings of private dwellings and other small buildings and serving the same purpose as rubble stone, brick, and monolithic concrete. Several firms reported one or more other products, such as silo blocks and sewer blocks, but these firms were so widely scattered that only the totals for the country are published. A few producers reported "art work" of different kinds, but this class of products is too incompletely represented to justify publication of the totals compiled.

In the following tables the figures are shown in as much detail as possible without disclosing individual returns.

Concrete stone produced in the United States in 1917.

ARCHITECTURAL CONCRETE STONE.

The quantity and value of architectural stone produced in 1917 and 1918 are shown in the first two columns of the foregoing tables. According to these tables the quantity decreased from 1,413,416 cubic feet in 1917 to 625,825 cubic feet in 1918—a decline of 56 per cent. Owing to the higher prices in 1918, the corresponding decrease in values was only 32 per cent. The value is that of the product f. o. b. factory.

The New England States, second in quantity of production in 1917, were first in 1918, although their production decreased more than one-half. The Middle Atlantic States, third in 1917, were second in 1918, their quantity decreasing more than one-third. The East Central States, first in 1917, were only fourth in 1918, Ohio's great decrease accounting for the change. These three districts produced 74 per cent of the total quantity in 1917 and 67 per cent in 1918. The other three districts decreased in production considerably in 1918, though in less proportion than the three leading districts.

The output was everywhere sold for comparatively local consumption. A number of producers sold their product in several cities within their own States and a few shipped to neighboring States. One producer in Connecticut reported his product as being shipped to New York City, Boston, Philadelphia, and Washington; another in Connecticut reported shipments to territory east of Buffalo; one in Massachusetts, to different New England States; one in Missouri, to Oklahoma, Texas, and Kansas; another in Missouri, to Kansas, Texas, Oklahoma, and Arkansas; and one in Texas, to Oklahoma, Arkansas, Louisiana, and New Mexico.

The average price per cubic foot was $1.12 in 1917 and $1.71 in 1918. The range in price was wide. Some products were not much more than concrete blocks prepared with unusual care and sold for as little as 15 cents a cubic foot in 1917 and 22 cents in 1918, and there was no sharp line of demarcation between these prices and those of ordinary concrete blocks. Others, of ornamental character and prepared in special molds, brought as much as $10 a cubic foot. The quantity sold for extraordinarily high prices, however, was far too small to affect the average price appreciably. One producer in New England manufactured only ornamental modeled architectural casts at $5 a cubic foot. A producer in the West, whose price in 1917 was $4 a cubic foot, stated that most of his product was more decorative than in other years, and that the average price was therefore twice as much. Another western producer reported "hand-finished artificial stone" from $1.50 to $3 a cubic foot. Prices reported by other important producers ranged from 50 cents to $2.50 a cubic foot.

The aggregates reported as used in 1917 and 1918 are listed in the table on pages 538–539. This table shows that relatively few manufacturers use granite, marble, or trap rock (diabase and basalt) to produce special textural effects in imitation of marble and granite. Some of those using miscellaneous aggregates, however, may produce similar results. A large number may manufacture products resembling sandstones and limestone in general appearance.

Business conditions during 1917 and 1918 affected producers of architectural concrete stone much the same as they affected producers of natural building stone. Labor and materials were both scarce

and much higher in price than before, and these conditions, together with war restrictions on transportation of "less essential materials," discouraged purchasers. Many producers reported that the war had put them temporarily or permanently out of business. The total production for each of these years is far below normal, therefore, but its proportion to the production of other building materials has probably not changed significantly.

CONCRETE BLOCKS.

The apparent great increase in production of ordinary concrete blocks—from approximately 11,416,000, valued at $1,548,379, in 1917 to approximately 18,063,000, valued at $2,299,760, in 1918—is largely if not wholly due to the more complete returns made in 1918. Even a small actual increase of building material would have been abnormal in 1918. There was little change in rank, however, among the six districts designated—New England, with an apparent increase of ninefold in quantity, gaining fourth place in 1918 at the expense of the Southeastern States, whose apparent increase was somewhat more than 60 per cent. The East Central and West Central districts were by far the most productive in each year, and each recorded an apparent increase in 1918. Only the Western States showed a decrease in quantity. The apparent gain in value was enough to give all sections except New England a recorded gain in total concrete products.

Individual reports regarding business conditions for concrete blocks were for the most part similar to those given for architectural concrete stone. A few producers, however, were favored by contracts to furnish blocks for Government housing projects.

The average price was 13.6 cents a block in 1917 and only 12.7 cents in 1918. In 1917 prices mostly range from 8 to 12 cents a block but in some places were as high as 17 and even 20 cents. In 1918 the prices of blocks were commonly from 12 to 35 cents, but the price of concrete bricks was commonly $12 a thousand, which accounts for the lower average price recorded for 1918. The different sizes of blocks and bricks and the failure of several producers to state sizes made it impossible to reduce the quantity of blocks and bricks to definite units, the only means of showing their actual and relative importance in the building industry. It is hoped that this will be possible in future reports.

MISCELLANEOUS PRODUCTS.

Reports of products of this class, other than architectural concrete stone and concrete blocks, were too scattered in 1917 to justify a statement of the quantities sold and their value. In 1918 also the reports were so scattered that tabulation by States was impracticable, but the totals for the entire country were as follows:

Miscellaneous concrete products sold in 1918.[a]

	Number.	Value.
Silo blocks, staves, and circles	183,004	$45,325
Sidewalk blocks and tile	67,171	14,567
Sewer blocks	67,000	8,040
Cistern blocks or tile	15,474	1,288
Well blocks, curbing, and circles	62,784	11,499
Corn cribs and crib piers	30,991	5,519
	426,424	86,238

[a] A very small production of draintile is omitted.

Here again failure of producers to state size or dimensions of the products lessens the significance of the figures for quantity. Of the 34 producers who stated the kinds of aggregates used in these products, all but two used sand and gravel; of these two one used granite screenings and the other sand and limestone. The three leading States in these products and the values of their outputs were Minnesota, $33,309; Iowa, $12,016; and Wisconsin, $12,407.

[a] Aggregates not reported from Texas, Nevada, and Oregon.

The marked increase in the number of firms reporting the use of sand and gravel is due to the more complete returns in 1918. The decrease in the number using granite, marble, and trap rock (basalt or diabase) reflects the decrease in production of architectural stone. The great preponderance of gravel over the other coarse aggregates is especially striking, and the districts where it is most used are those which lead in output of concrete blocks. Granite, marble, and trap rock are relatively most used in New England, the leading district in output of architectural concrete stone. Granite, largely for facing, is also much used in the East Central States and marble in the Middle Atlantic States. Limestone is mostly used in the East Central States. Miscellaneous aggregates include "flint" and "chats" (tailings from zinc mines, mostly in the Joplin region, Mo.), slag screenings, cinders, and unnamed crushed stone. One producer reported "coquina shell and beach sand." Feldspar and mica, derived from coarse-grained granite or pegmatite and used to face blocks imitating granite, are included with granite.

It would be interesting to know what proportion of the Portland cement, sand, gravel, and crushed stone produced during 1918 entered into the different products considered in this report, but inadequacy of the statements of quantity and uncertainty as to the proportions of cement and aggregate used make even a rough estimate impracticable. If this first report on the production of concrete stone and related products proves to be of sufficient interest and usefulness to the building industry, an effort will be made to obtain such additional information.

STRONTIUM.

By George W. Stose.

GENERAL REVIEW OF THE INDUSTRY.

The strontium industry in the United States, which suddenly sprang into importance at the beginning of the European war, seems to have reached its climax in 1918. Prior to 1915 the consumption of strontium in this country, so far as the records of the United States Geological Survey show, was small and its ores had been mined at only a few places in the country and in very small quantities. Until 1915 strontium was used chiefly in the manufacture of red fire in pyrotechnics and in railroad flares and fusees, but during the European war it found a larger and wider field of usefulness. Not only was it employed in night signals at the military front and at sea, but the congestion of freight in our own country and the need of every precaution in safeguarding the shipments of war materials greatly increased the practice of railroad signaling by fusees and flares. Whereas 2,000 short tons of crude ore was sufficient to meet the annual requirements before the war, it is estimated that about 4,000 tons was used in 1918.

For 20 years prior to 1915 the value of strontium salts imported averaged about $450 a year, and in 1914 it amounted to only $1,016. The imports gradually increased in the following years and the value reached $23,216 in 1917. This very marked increase resulted in part from the higher price of the product, but largely from an increased demand for the material in anticipation of future requirements, especially if war activities should cut off the foreign supply. Interest in the domestic deposits of strontium ore reflected this attempt at preparedness, and early in 1916 deposits in California and Arizona were mined and strontium ore was shipped to two manufacturing plants in southern California which began to make strontium nitrate. In the later part of 1916 another manufacturing plant began making strontium salts at Seattle, Wash., using ore mined in that State. At the end of 1916 the British Government placed an embargo on all strontium compounds, but its effect was not felt at once in the United States, for the imports of strontium salts greatly increased in the first half of 1917. In the last half of the year, however, the imports were relatively low, and in 1918 their value dropped to less than $2,500. Not only did the imports of strontium salts decline, but the production of crude strontium ores in the United States also fell off in 1918 to a few hundred pounds. The manufacture of strontium salts, on the other hand, was greatly increased during 1918, the manufacturing plants evidently using stocks of both foreign and domestic crude ore purchased in previous years.

It is impossible at this time to predict the future of the strontium industry in this country. The production of strontium salts seems permanently established in several plants located in the Eastern States, but these plants will probably depend for their supply of crude ore chiefly on imports from England because of the large and accessible deposits that occur there and the cheapness of ocean transportation as compared with rail freight rates from the Western States, where the known workable deposits of this country occur. The production of strontium salts at three manufacturing plants in Pacific Coast States in 1916 and 1917 was temporary, for the plants have closed down and the mining of crude ore in two of these States has for the present ceased.

PRODUCTION OF CRUDE ORE.

The production of crude strontium ore in the United States in 1918 apparently was very small. The following table permits comparison with the production of previous years:

Crude strontium ores mined and sold in the United States, 1916–1918, in short tons.

Mineral.	1916	1917	1918
Celestite	240	3,630	0
Strontianite	10	405	400

No ore was mined in 1915. The ore mined during 1916, 1917, and 1918 came chiefly from California, but some came from Texas, Arizona, and Washington. The average price received at the mines for celestite in 1917 was $21.75 a ton, and for strontianite $38.15. The price received for strontianite increased to $50 a ton in 1918.

PRODUCTION OF STRONTIUM SALTS.

Three companies in the United States reported the manufacture of strontium salts from crude ore during 1918. Strontium nitrate was the chief product made, but a considerable part of the product was carbonate. Small quantities of chloride and oxalate also were manufactured. The production of strontium nitrate, carbonate, chloride, and oxalate in 1916 was 2,006,000 pounds; in 1917, 2,499,676 pounds; and in 1918, 4,927,000 pounds.

IMPORTS.

The only crude strontium mineral reported as imported in 1918 was celestite, all of which came from England. If the mineral strontianite was imported, it was not separately reported but was included with manufactured strontium carbonate and other salts by the Bureau of Foreign and Domestic Commerce. The quantity of celestite reported as having been imported during the last three years has averaged approximately 2,100 short tons a year. The quantity received in 1917 was about 1,700 tons and in 1918 it exceeded 2,600 tons.

Value of strontium carbonate, oxide, and protoxide[1] imported into the United States, 1895–1918.

1895–1913 (average)	$447	1916	$11,049
1914	1,016	1917	23,216
1915	6,411	1918	[2] 2,459

The increase in the value of the imports for 1916 and 1917 was only in part due to the increased quantities imported, for the price of the products also increased greatly, as is shown in the table of prices given below. However, the value of the imports for 1917 was greatly in excess of that of any previous year. The marked decrease in imports in 1918 was due largely to the embargo placed on strontium salts during the European war.

The following table shows the marked change in prices of strontium carbonate and strontium nitrate quoted in New York:

Prices of strontium nitrate and strontium carbonate[a] in New York, 1914–1918, in cents per pound.

Salt.	1914	1915	1916	1917	1918
Strontium nitrate	7½–8	15–17	22–23	40–45	25–30
Strontium carbonate:					
Technical	(b)	(b)	(b)	(b)	40–45
Chemically pure	(b)	(b)	(b)	(b)	55–60

[a] Oil, Drug, and Paint Reporter Yearbook, 1918.
[b] Not quoted prior to 1918.

The decrease in the price of nitrate in 1918 practically to the price which prevailed in 1916 was apparently due to control by the Government during the war.

The following price list of salts of strontium, most of which are used largely by druggists and the medical profession, is of less interest to the producer of crude strontium ore because only a few of these salts are made direct from crude ore, the others being secondary salts made from the primary salts.

Price list of strontium salts.[3]

	Per pound.		Per pound.
Acetate, granular	$1.30	Hydroxide, powder	$1.15
Arsenite, powder	2.75	Iodide, granular	3.65
Bromide, crystalline and granular	.96	Lactate, granular, powder	2.45
Bromide, dried, powder	1.37	Nitrate, granular	.47
Carbonate, precipitate, technical	.50	Nitrate, granular, chemically pure	.70
Carbonate, pure, powder	.70	Oxalate, powder	2.00
Chloride, granular	.45	Peroxide (dioxide), powder	2.60
Chloride, dried, powder	.78	Phosphate, powder	1.25
Chloride, crystalline, chemically pure	.65	Salicylate, powder	1.25
Formate, granular	2.00	Salicylate, from oil, powder	5.20
		Sulphate, powder	.60
		Sulphide, powder	1.10

[1] Value of "oxide of strontium, protoxide of strontium, and strontianite or mineral carbonate of strontium" imported for consumption into the United States, compiled from the records of the Bureau of Foreign and Domestic Commerce.
[2] This figure seems in error, as the value given for the fourth quarter ($356) does not harmonize with the quantity reported to have been imported (185,920 pounds).
[3] Powers, Weightman & Rosengarten Co., Philadelphia, price list, February 1, 1918.

USES AND MARKET.

Strontium is used in the form of its salts in several industries, especially in the manufacture of fireworks, drugs, and medicine. The principal salts manufactured in the United States in 1918 were strontium nitrate (SrN_2O_6) and strontium carbonate ($SrCO_3$), which are used chiefly in the production of red fire or light in pyrotechnics, flares, fusees, signal shells, and signal lights. Small quantities of chloride and oxalate were reported manufactured from crude ore in 1918. Many other salts were probably manufactured, but mostly as secondary products from the primary salts above mentioned. The acetate, lactate, bromide, iodide, arsenide, phosphate, and other salts of strontium are used in drugs and medicine. In Europe large quantities of oxide and hydroxide of strontium are used in refining beet sugar, but this process is not at present employed in the United States. A small quantity of strontium is alloyed with copper in making castings to free them of blowholes caused by included gases.

Fireworks and signal lights are manufactured in the United States almost exclusively near the Atlantic seaboard, and the demand for crude ore is therefore in the Eastern States. It has been difficult, consequently, to find a market for the domestic strontium ore, the workable deposits of which have so far been found only in the far West and which can not in normal times compete in price with the celestite obtained from England because of high freight charges unless it is protected by a tariff. During the war, however, some western ore was shipped to eastern factories.

DEPOSITS OF STRONTIUM ORES IN THE UNITED STATES.

The known workable deposits of strontium ore in this country are in Arizona, California, Texas, Utah, and Washington. Other deposits of doubtful value occur in several other of the Western States and in a few States east of Mississippi River. Most of these have been described in some detail by James M. Hill in Mineral Resources of the United States, 1916, Part II, to which the reader is referred. New finds have been reported as follows:

Utah, 25 miles southeast of the town of Green River, Grand County. J. T. Pardee, geologist, of the United States Geological Survey, reports that at this place celestite forms lenticular beds 6 inches thick associated with gypsum and limestone in the middle of the St. Elmo formation at the Colorado Fuel & Iron Co.'s manganese mine. Samples of the mineral are of excellent grade.

Nevada, 7½ miles south of Goldfield. Large deposits of strontianite are reported to have been discovered by G. L. Diffenbaugh, of Goldfield. The samples of the mineral sent to the Geological Survey, however, were largely calcite.

ASBESTOS.

By J. S. Diller.

DOMESTIC OUTPUT.

The asbestos mined and sold in the United States in 1918 amounted to 1,002 short tons, valued at $124,687, about 60 per cent of the quantity and 25 per cent of the value of the product marketed in 1917, which was 1,683 short tons, valued at $506,056. Although there was a decline in both total quantity and value in 1918, there was an increase in the unit value of several grades. The lowest grade sold for about $15 a ton in both years, but good spinning grades which brought $500 a ton in 1917 were sold for about 20 per cent more in 1918. In States that reported sales in both years declines in output were shown in all grades except that from Maryland, which is used for chemical filters, but the decline in relative quantity produced was greatest in the spinning grades. However, the proportion of spinning fiber to lower grades produced in the United States is still much higher than in Canada. The demand for asbestos was increased by the war, but asbestos was not classed in the United States as a war mineral, and its production and distribution were delayed by embargoes and other unfavorable conditions. Six States produced asbestos in 1918—Arizona, California, Georgia, Maryland, North Carolina, and Oregon. Georgia was the largest producer, yielding, however, only low-grade fiber; North Carolina ranked next, also producing low-grade fiber; California ranked third, producing a better grade of mill fiber; and Arizona ranked fourth, with five more or less active producers, whose output is chiefly spinning fiber.

The principal feature of the asbestos industry in 1918 was the decline in production notwithstanding the increased demand and higher prices, as compared with those of 1917. This condition was due to the war and resulted from the scarcity of labor and the restraints of trade.

Domestic asbestos marketed in the United States, 1913–1918.

Year.	Quantity (short tons).	Value.	Year.	Quantity (short tons.)	Value.
1913	1,100	$11,000	1916	1,479	$448,214
1914	1,247	18,965	1917	1,683	506,056
1915	1,731	76,952	1918	1,002	124,687

VARIETIES AND TYPES OF ASBESTOS.

The most important characteristics of asbestos are fibrous structure, tensile strength, and resistance to heat. It will not burn and is an excellent material for protection from fire. Being a slow conductor of heat, it is used to conserve heat by preventing radiation, especially about steam pipes and boilers.

Commercially the name asbestos is used to include all varieties of minerals that are so fibrous as to be thereby rendered useful. The same minerals occur also in massive nonfibrous varieties, each known by a distinctive name. Strictly speaking asbestos is fibrous amphibole, although by far the greater portion of the asbestos of commerce is fibrous serpentine, which is properly called chrysotile. Amphibole asbestos was produced in Maryland, Georgia, and North Carolina in 1918; serpentine asbestos in the Western States.

There are three structural types of asbestos—cross fiber, slip fiber, and mass fiber. Cross-fiber asbestos occurs in veins, and the fiber runs across the veins. This type is well illustrated by the veins of asbestos (chrysotile) in the altered peridotite of Thetford, Canada, and also by similar veins with serpentine in certain limestones of Arizona. This is the most abundant type, especially of chrysotile, yielding by far the greater portion of all grades of commercial fiber.

Slip-fiber asbestos occurs in planes along which the rocks have slipped against each other and given direction to the fiber. The fiber lies parallel to the slipping planes and is commonly some variety of amphibole. It yields a relatively small quantity of commercial asbestos.

Mass-fiber asbestos is rock wholly made up of irregularly arranged bundles of fibrous amphibole. The asbestos of this type is generally brittle and of low grade. It is well illustrated by the deposits mined in the Sall Mountain region of Georgia.

ASBESTOS IN THE UNITED STATES.

ARIZONA.

Chrysotile asbestos was discovered in the Grand Canyon of Arizona about 1900. The Hance Asbestos Co. was formed and brought this remarkable occurrence to public attention. It crops out on both sides of the Grand Canyon, but especially on the north side opposite Grand View. Joseph Hyde Pratt, of the United States Geological Survey, examined the deposits and described them in Mineral Resources for 1904, pages 17–20. Some years later W. W. Bass reported similar deposits in the Grand Canyon 20 miles west of Grand View. The Bass deposits are briefly described in Mineral Resources for 1907, pages 12–13, and also by L. F. Noble in United States Geological Survey Bulletin 549, pages 58–59, 1914.

At both localities in the Grand Canyon asbestos occurs in cross-fiber veins that lie with serpentine in limestone approximately parallel to its stratification and within a short distance of its contact with intruded diabase. A small quantity of asbestos has been mined at each locality in the Grand Canyon, but production has not been maintained, chiefly on account of the cost of mining and of getting the product to market.

A chemical analysis of the Grand View asbestos was made by the Geological Survey in 1912, and attention was called to its remarkably low content of iron, which renders it especially valuable for electrical insulation.

In 1903 a deposit of chrysotile was found in southern Arizona, at the head of Pinto Creek, 23 miles west of Globe, where M. L. Shackelford located claims. The asbestos is said to be of fine quality, and fibers are said to range from a fraction of an inch to 2 or 3 inches in length. No development work or production of asbestos has been reported from this locality.

In 1913 Fred Patee informed the Geological Survey of a new locality of chrysotile in Arizona, on Ash Creek, about 40 miles northeast of Globe. The writer visited the locality under the guidance of Mr. West, one of the locators, and published an account of the deposit in Mineral Resources for 1913, part 2, pages 342–347. The writer visited the locality again in 1917 and in 1919 and found active asbestos mining in an area about 60 miles in length from northwest to southeast and 25 miles in width. He examined that part of the asbestos field lying west of the San Carlos and Apache Indian reservations, where mining operations were carried on by the Arizona Asbestos Association on Ash Creek, by the Penn Asbestos Mining Co. and the Colorado-Arizona Mining Co. just south of Salt River, by the American Ores & Asbestos Co. at the head of Pocket Creek in the Sierra Ancha, at the Roberts mine on Reynolds Creek, at the Sloane mine on the slope east toward Cherry Creek, and by the Alene Asbestos Association on a branch of Canyon Creek. The whole area lies east and northeast of Globe and the Roosevelt Reservoir. The mining localities are all west of the western border of the San Carlos and Apache Indian reservations. The asbestos area within the reservation has not been prospected, although it is reported on good authority that asbestos occurs at several localities within them. Some asbestos of both high and low grade is reported as occurring on the new Winkelman road, 21 miles southeast of Globe, where five claims have been located by Antonio Brown, but no fiber has been marketed from this place. H. P. Wightman, of Globe, reports asbestos near Dudleyville, about 20 miles south of Globe, but more definite information is not available.

Arizona Asbestos Association, of Globe, Ariz.—This company (H. V. Snell, president; N. A. Nelson, superintendent) opened the mines on Ash Creek in 1914 and began a production which, except for a few months early in 1918, has continued ever since.

The area, including the numerous prospects of asbestos in the Ash Creek region, is about 2 miles long by two-thirds of a mile wide and embraces nearly 30 claims on the steep slopes on both sides of Ash Creek canyon. The horizontal sandstone and limestone strata, as well as the sheets or sills of igneous diabase, intruded into but mainly between the strata, crop out on the canyon slopes.

The asbestos is found in cross-fiber veins in the limestone only, but near its contact with the diabase, which is regarded as having caused the development of the serpentine and chrysotile by altering the limestone. The asbestos is mined by tunneling into the limestone along the asbestos. The Ash Creek mine has about 10,000 feet of underground workings arranged in four levels. The longest tunnel reaches a point about 600 feet into the mountain on the east.

The miners save not only the crude fiber but also the rock that is sufficiently rich in mill fiber to justify milling at the mine.

The fiber ranges from a small fraction of an inch to several inches in length. All that is more than half an inch in length may be used for spinning and is included among the crude. The shorter fiber is mill fiber. The asbestos veins are generally arranged in groups in the limestone near its contact with diabase. A common form of occurrence in the Ash Creek mine has two groups of three to five small veins each, separated by serpentine and some limestone. The two groups where most fully developed have a combined thickness of about 4 feet and are separated by 4 feet of limestone which contains more or less nodular serpentine. Both groups of veins may be worked by one tunnel, and in rich portions of the mine asbestos may constitute 10 per cent of the rock removed. Some veins may be traced 100 feet or more with but few interruptions. In places, however, they wedge out, but they may come in again beyond at the same horizon if the limestone and diabase continue in the same relative position.

On Ash Creek the asbestos is developed generally in the basal portion of the limestone where it rests on diabase, but at several places it is developed in the upper portion of a limestone that is overlain by diabase.

In the Ash Creek mine asbestos has been mined for 600 feet into the mountain on the east. Beyond this point it continues eastward into the mountain, evidently for a considerable but unknown distance, which will depend on the continuity of the same relation between the limestone and the diabase. To prospect, develop, work, and drain most conveniently the portion of the mine farthest east from the entrance two tunnels have been run into the diabase; they are already in about 500 feet and are about 60 feet below the level of the limestone.

The outlet of the mine is on a steep slope, about 100 feet above the level of the creek. The slope affords an excellent dumping ground and mill site. Near the outlet of the mine a small mill, consisting of rock crusher, cyclone, and screens, prepares four grades of mill fiber for the market. The output of crude fiber is much greater than that of mill fiber, a feature that is of special economic interest inasmuch as the reverse situation exists in the asbestos mines of Canada and Russia.

About 140 men were employed at the mine in September, 1919. The mine is 41 miles from the nearest railroad shipping point, and truck roads are difficult to maintain. Asbestos not being a war mineral, embargoes on railroad shipment and labor difficulties incident to the war greatly reduced the production in 1918.

Penn Asbestos Mining & Refining Co.—This company began operations on about 20 claims a few miles north of the Ash Creek mine, on the upper part of Bald Head Creek. A limestone 50 feet in thickness rests on a thick sheet of diabase, and in the limestone near the contact a number of asbestos veins are exposed. They range in thickness from half an inch to a thin film. There is a considerable amount of milling rock but at the time of the writer's visit (Sept. 8, 1917) there was very little No. 1 crude in sight. Since then the underground workings have been greatly extended. A small production was reported in 1918 but in 1919 the mine was

closed. The most promising fiber seen in the mines operated by the Penn Asbestos Mining Co. was on the Eagle claim north of 72 Spring, but the fiber was rather harsh. The Shanley group of claims and numerous others in the same region were not examined by the writer.

Colorado-Arizona Asbestos Mining Co.—A small production has been reported by this company on the Larson property, which lies on the steep slope 1,000 feet above Salt River, near the mouth of Cherry Creek. Three tunnels have been run into the basal portion of the limestone along the asbestos belt near the contact with the underlying diabase. At the time of the writer's visit (Sept. 8, 1917) there were three tunnels opened in somewhat broken and faulted limestone. The fiber looked best in the middle tunnel, a short distance from the opening. The 8-inch fiber belt had about 3 inches of good spinning fiber and appeared a promising prospect. However, as the mine was closed, the deeper underground workings could not be examined. East of the mine opening the continuity of the limestone is broken by faulting. The limestone is nearly 100 feet thick at this point and is overlain by a thick mass of sandstone, as at Ash Creek. The diabase appears to extend most of the way down to the river at Salt Lick. This property is said to be in litigation. It is being developed and operated under the direction of E. E. Miller.

American Ores & Asbestos Co.—This company was organized and its property developed by Charles F. Sloane, its first president. The company owns 28 claims near the head of Pocket Creek, about the summit of Coon Creek Butte, the southern portion of the Sierra Ancha, 8 miles northeast of the Roosevelt Reservoir. Its mine was opened in 1916 and actively operated in 1917 and 1918. Only crude fiber was shipped. No mill has yet been erected, but much mill rock has been accumulated in the process of mining. The asbestos occurs at two horizons in limestones separated by a thick sheet of diabase, and the upper limestone, about 30 feet in thickness, is overlain by a thin sheet of diabase. The upper zone is mined along a line of nearly a dozen openings for about a third of a mile. The lower zone, which is at the top of a limestone 150 feet thick, has thus far yielded only milling rock. In the mine in the Sierra Ancha the asbestos is along the contact of the diabase overlying the limestone but in the Ash Creek mines it is generally along the contact of diabase beneath the limestone. Mr. Sloane's interest in the mine has recently been sold to the Raybestos Co., of Bridgeport, Conn., which, with the United States Asbestos Co., of Lancaster, Pa., under the management of E. B. Shutts and H. E. Hacker, controls the mine. Men are at work (September, 1919) preparing to operate the mine and, if found advisable, erect a mill.

Roberts mine.—Reynolds Creek cuts a deep gash in the western slope of the Sierra Ancha, exposing the horizontal sandstone, limestone, and diabase that extend northward from the Pocket Creek region where the American Ores & Asbestos Co.'s mine is located. A Los Angeles company, managed by W. L. Roberts, began operations on Reynolds Creek, 2 miles above the road crossing the creek near some claims prospected in 1917 by B. L. Rogers, who sold about half a ton of fiber. The Denver Arizona Asbestos Mining Co. may operate its property in the same region.

Sloane mine.—Charles F. Sloane has recently acquired five claims from Clyde Kennedy on the eastern slope of the Sierra Ancha, locally

known as Horse Mountain. The limestone is about 100 feet thick. The upper part is massive and the lower part thinner bedded. It is overlain, underlain, and intruded by diabase. There appear to be three belts of asbestos, 10 to 15 feet apart, in the upper portion of the limestone. Some of the asbestos is harsh, but most of it is of good spinning grade. Some fiber was shipped from this point in 1918 and arrangements are being made for further development and production. The locality is reached only by a rough trail over Horse Mountain, which is composed of sandstone forming prominent cliffs above the asbestos horizon.

The bed of asbestos-bearing limestone beneath the cliffs is nearly horizontal and extends north along the face of the Sierra Ancha and east into the upper valley of Cherry Creek, where it forms broad mesas between box canyons. Many asbestos claims have been prospected and located in the upper portion of Cherry Creek valley.

Alene Asbestos Association.—From the upper portion of the Cherry Creek region the asbestos-bearing limestone and associated rocks extend east into the drainage of Canyon Creek, where the mine of the Alene Asbestos Association is being operated on a small scale by Earle Pierce, who packs the output directly to Globe, a distance of nearly 50 miles.

There are eight claims around the edge of a limestone mesa that lies between two of the upper tributaries of Canyon Creek. Nearly a dozen tunnels have been run into the basal portion of the limestone, some of them 150 feet, just above its contact with diabase that underlies the mesa. Pierce's camp is on Sloane Creek, in the northwestern portion of the group of claims, where the exposures seem most promising. There are two belts of asbestos separated by about 4 feet of thin-bedded limestone. The upper asbestos belt has a maximum thickness of 10 inches and contains much good fiber; the lower belt, 3 inches thick, has 2 inches of fiber in places. In its richest parts the rock removed in making the tunnel contains about 10 per cent of asbestos, but generally the content is much less—1 to 3 per cent—and locally the asbestos disappears altogether. However, continuity of the serpentine or asbestos belt is the more frequent occurrence. When asbestos of good quality and in considerable quantity is in sight its removal is easily contracted for, but it is much more difficult to provide for the development work necessary to keep the mine going when the asbestos declines. For this reason the most successful asbestos mining of the region is managed by a strong company able to provide for the prospecting necessary as the mine advances. Experience has shown that although the quantity of asbestos is small, as compared with that of the Canadian mines, and the cost of mining is high, yet the superior quality of the fiber for insulating purposes should make it sufficiently valuable to justify the necessary expenditure for development.

Apache and San Carlos Indian reservations.—The Apache and San Carlos Indian reservations have recently been opened for mining metalliferous minerals, but not for mining asbestos. There is reason to believe that asbestos occurs in the reservations and in such quantity and quality as to render it especially valuable in commerce. No effort should be spared on the part of the Government to make this needed resource available in the reservations.

All the asbestos deposits of the Globe region described, except those of the Sierra Ancha, lie near the western border of the reservations.

The rocks, however, are horizontal and extend east into the reservations. This is true of the mines of the Arizona Asbestos Association, the Penn Asbestos Mining & Refining Co., and the Alene Asbestos Association.

It is credibly reported that Antonio Brown, of Miami, Ariz., has asbestos claims on the Winkelman road, 21 miles southeast of Globe.

A deposit of asbestos within the San Carlos Reservation, northeast of Cassadaro Spring, is reported to be quite as promising as any other that has thus far been opened in Arizona.

An estimate of the relative importance of the Arizona asbestos field is indicated by the fact that in the last four years (1915–1918) it has produced about 1,900 tons of chrysotile, chiefly of spinning grade.

CALIFORNIA.

Notwithstanding the general decline in the domestic production of asbestos, the production in California in 1918 increased about 30 per cent over that of 1917 on account of the local demand. The principal producer was the Sierra Asbestos Co., of Nevada County. No production of crude fiber was reported, but four grades of mill fiber were prepared and used by the John D. Hoff Co., of Oakland, in making flooring, stucco work, steam-pipe covering, and asbestos cement.

A small production of asbestos was reported from Calaveras and Alameda counties. A company is said to have commenced operations on an asbestos property at the head of Los Gatos Creek, 25 miles northwest of Coalinga, in Fresno County, which shows fine crude fiber.

Prospects have been opened in Sierra, San Benito, Placer, Fresno, Napa, Shasta, and other counties of the State, but the fiber is too short for spinning and, for the most part, can not be worked profitably, although some crude occurs which is $1\frac{1}{4}$ inches long and, if in sufficient quantity, may be graded separately.

OREGON.

The Oregon Asbestos Mine Co., of Portland, Oreg., operated for a short time a mine a few miles north of Mount Vernon in Grant County. The output, which is reported small, contains three grades of material. The lowest grade was asbestic and occurred in the largest quantity.

WYOMING.

The asbestos deposits of Natrona and Fremont counties, Wyo., have already attracted much attention but have thus far yielded only a small quantity of commercial asbestos. In the report for 1917 attention was called to the deposit of the American Fireproofing & Mining Co., about 28 miles south of Lander. A small quantity of spinning fiber was obtained here and manufactured into yarn and wicking. The mine was practically closed in 1918, and the small production is reported to have been kept in storage unsold.

Recently a partial analysis of an asbestos sample collected by the writer at this mine in 1917 has been made by Roy L. Jones, of Pittsfield, Mass. The sample included the full length (about an inch) of the fibers, which extend completely across the vein. The ends of the fiber are somewhat darker than the middle portion, which

is bright amber-colored. Mr. Jones reports [1]: "We clipped off the ends of the fiber. A separate analysis of the material removed showed 3.79 per cent of Fe_2O_3 although the fiber from which the ends were clipped contained only 1.27 per cent of Fe_2O_3." Mr. Jones states further: "Only ferric iron was present. We did not find any evidence of the iron in ore particles. It seemed to be chemically combined in the fiber."

GEORGIA.

In 1917 there were two companies mining and milling mass-fiber amphibole asbestos (anthophyllite), but owing to the demands of the war only one company, the Sall Mountain Co. of Georgia, continued its operations through 1918. It is, however, gratifying to note that its production remained about the same as in 1917. The best rock mined is that which is altered and partly softened by weathering. About 90 per cent of the rock mined appears in the finished asbestos product which is used largely in the manufacture of paints, fireproof cements, and other similar objects.

MARYLAND.

The restrictions on commerce resulting from the war cut off the supplies of amphibole asbestos from Italy used for chemical filters. The demand thus produced led to the discovery of a good supply of amphibole slip fiber in the weathered metamorphic rocks of Maryland. The unweathered fibrous rock is hard and brittle, but with weathering and disintegration it becomes more flexible, though retaining some textile strength. It can not be woven, but it so intermingles as to form a filter mat. It is mixed, washed, and treated chemically by the Powhatan Mining Co. so as to prepare it for Gooch filters. The quantity available for mining at any one place is generally small. The quantity of treated fiber sold is small and must bring high prices to attain financial success.

NORTH CAROLINA.

Sales from North Carolina were reported in 1918 for the first time in several years. The product was amphibole asbestos mined at Cane River, Yancey County, by W. C. Doak and N. C. McFalls.

IDAHO AND VIRGINIA.

A small quantity of amphibole asbestos was produced in Idaho and Virginia in 1917, but none was produced in 1918.

PRICES.

The strong demand for asbestos in 1918 caused a continued rise in prices for practically all grades of Canadian asbestos in the New York market, as quoted below by the Bennett Martin Asbestos & Chrome Mines (Ltd.), 220 Broadway, New York City.

Range of New York prices per short ton for Canadian chrysotile fiber, 1913–1918.

	1913	1914	1915	1916	1917	1918
No. 1 crude	$320–$350	$350–$375	$350–$400	$350–$1,250	$700–$1,500	$1,200–$2,000
No. 2 crude	200– 225	225– 250	225– 275	250– 900	500– 900	700– 1,200
No. 1 fiber	100– 125	100– 125	110– 150	150– 350	150– 450	400– 600
No. 2 fiber	75– 100	75– 100	80– 125	75– 150	75– 150	250– 300
Shorter fibers	10– 30	10– 30	10– 30	15– 60	18– 75	18– 125

[1] Letter dated August 2, 1919.

Owing to the small production of the various grades of fiber in the United States there is no established price for them in the regular markets, but they are sold to consumers who, appreciating their value, are endeavoring by fair prices to encourage production and develop the domestic asbestos industry.

In Canada in 1918 the average price of crude fiber sold was $671.28 a short ton, an increase of $161 over the average sales price of crude in 1917. The average price in 1918 of the mill fiber was $46.88 a ton and of asbestic $2.03.

Owing to the fact that in practically all the Arizona fiber the harsh and the soft material are intermingled in such a way that it is difficult to separate them, these fibers do not bring as high prices as the Canadian. Soft Arizona fiber sells at $850 to $1,250 a ton, according to its length, and the harsh Arizona fiber at $350 to $600 a ton. The shorter fibers or mill rock have about the same value as the Canadian shorter fibers.

IMPORTS.

The United States is the world's largest manufacturer of objects made of asbestos. The greatest source of supply of raw asbestos is the Province of Quebec, Canada, from which it is imported into the United States free of duty. The total imports of unmanufactured asbestos in 1918 amounted to 137,700 short tons, an increase in quantity of about 2.7 per cent over the imports of 1917, but on account of the advance in price during the year the increase in the total value of imports of asbestos from Canada was about 50 per cent. Of the total quantity of asbestos imported in 1918 nearly 98 per cent came from Canada and the remaining 2 per cent came chiefly from South Africa. The imports from Canada constituted about 95 per cent of the total asbestos mined and sold in Canada in 1918.

Asbestos imported into the United States in 1917 and 1918.[a]

[a] Figures compiled from records of Bureau of Foreign and Domestic Commerce, U. S. Department of Commerce.

EXPORTS.

The total exports of unmanufactured asbestos in 1918 amounted to 697 short tons, valued at $51,053, a decrease of approximately 1.6 per cent in quantity and of 56 per cent in value, as compared with 708 tons, valued at $116,580, in 1917. Unmanufactured asbestos was exported from the United States to Canada, Italy, England, and France, and the value per ton ranged from $13.41 to $189. Evidently the material was not crude but mill fiber. Manufactured asbestos was exported from the United States to 67 countries to the total value of $2,493,325, a figure which illustrates the large interest of the United States in manufacturing asbestos.

FOREIGN DEPOSITS AND PRODUCTION.

General statement.—The principal asbestos-producing countries, named in their order of importance, are Canada, South Africa, and Russia. Although nearness to market and abundance of supply of asbestos are most important factors in determining the sources of our imports, especially from Canada, it is chiefly the suitability of certain varieties of asbestos for special purposes that brings amphibole asbestos from Italy for chemical filters and the blue asbestos (crocidolite) from South Africa for electric welding and for spinning.

Canada.—Canada has furnished for many years the larger part of the world's supply of asbestos. The Canadian material is wholly chrysotile asbestos. The output has increased greatly during the last few years up to 1917, and prices have advanced even more rapidly than the output. In 1918, however, owing to delays incident to the war, the production of crude asbestos decreased. Asbestos is produced from cross-fiber veins in peridotite in the Province of Quebec at Black Lake, Thetford, Robertsonville, Coleraine, East Broughton, and Danville.

In 1918 the output in Canada included 4,313 short tons (3,913 metric tons) of crude asbestos, of which 3,692 short tons sold for $2,478,363, an average price of $671.28 a ton (3,349 metric tons at $740 a ton), and 139,143 short tons (126,231 metric tons) of mill stock, of which 137,770 short tons sold for $6,458,442, an average price of $46.88 a ton (124,985 metric tons at $51.67 a ton). There was also a production of 16,734 short tons of asbestic in 1918, which sold for $2.03 a ton (15,181 metric tons at $2.24 a ton). The total Canadian production of asbestos in 1918 was 141,462 short tons (128,334 metric tons), all chrysotile, of which more than 95 per cent was brought into the United States and sold for direct consumption or for manufacture into various objects.

Russia.—Russia has for many years ranked next to Canada in the production of asbestos from similar deposits, but has lately lost its rank to South Africa, where asbestos occurs in greater variety. The principal deposits in Russia occur on the eastern slope of the Ural Mountains, near Ekaterinburg. Other deposits occur in Siberia, at Irkutsk and Yenisei. The output of Russia increased from 8,010 short tons (7,267 metric) in 1905 to a maximum of 19,284 short tons (17,494 metric) in 1913; since then its production has declined somewhat. Imports to the United States ceased in 1915. The deposits are extensive, and under favoring conditions may yield a large output.

South Africa.—South Africa excels all other countries in the variety of the asbestos it furnishes for the world's market from Rhodesia and the Union of South Africa. There are at least three varieties of asbestos of commercial importance in South Africa—chrysotile, crocidolite, and amosite. Chrysotile is a form of serpentine asbestos and the other two are forms of amphibole asbestos. Chrysotile occurs not only, as in Canada, in serpentine derived from the alteration of peridotite, but also, as in Arizona, in serpentine derived from the alteration of limestone. The countries containing important deposits of asbestos are Rhodesia, West Griqualand, and the Transvaal. Less important deposits occur in Natal.

Rhodesia produces white chrysotile asbestos of excellent quality, which compares favorably with the Canadian material. The output comes from two mines in Victoria and is shipped generally by way of Beira, in Portuguese South Africa. The output in 1913 was only 290 short tons, valued at about $78 a ton (263 metric tons at $86). In 1917, four years later, the output had increased to 9,562 short tons, valued at $91 a ton (8,675 metric tons, at $100 a ton). Owing to the war, however, production decreased about 10 per cent in 1918.

Crocidolite has long been known in the Asbestos Mountains of West Griqualand. It occurs in cross-fiber veins inclosed in a great succession of thinly bedded, dark-brown ferruginous shaly rocks, and the continuous fibers of crocidolite are generally not less than 2 to 6 inches in length.[1] The better quality occurs in hard rock. It is remarkable not only on account of its blue color but also for its high content of peroxide of iron. The merits of crocidolite have been slowly recognized, but it is now in general use for many purposes.

The output during the year 1898 is said to have averaged about 100 tons a month. Kafir labor is employed. About 25 per cent of the fiber is an inch or more in length. The Cape Asbestos Co. is the chief producer and consumer of blue asbestos at its factories in England, Germany, Italy, and elsewhere. The business of the Cape Asbestos Co. expanded so much in 1918 that its plant at Basking, England, had to be enlarged.

The mode of occurrence and distribution of asbestos in the Union of South Africa, especially in the Transvaal, have been well described recently by A. L. Hall.[2] Three varieties of asbestos occur there—chrysotile, crocidolite, and amosite. The white to pale-green chrysotile is remarkable in being like that of Arizona in its association. It occurs in altered dolomite near the upper contact of a diabasic sill in the Carolina district. The length of the fiber ranges from 6½ inches downward and is usually from one-half to three-fourths of an inch. The quantity available is said to be limited—only one mine furnished a steady output in 1917—and about half is said to be spinnable. A chemical analysis of the Carolina chrysotile shows that it contains no iron, whereas that of Canada has 2.53 per cent of iron oxides.

The lavender-blue crocidolite is reported as occurring in large quantities as cross-fiber veins parallel to the bedding in banded ironstone a little above the base of the Pretoria series. The greatest length of the fiber is several inches, and the proportion of available fiber is uncertain.

[2] Hall, A. L., Union of South Africa Dept. of Mines and Industries Geol. Survey Memoir No. 12, and also in the South Africa Geol. Soc. Trans., vol. 21, 1918.

A third variety of asbestos, designated as amosite, is a grayish-white monoclinic iron amphibole, which at the present time forms the bulk of the output of asbestos in the Lydenburg and Pietersburg districts; and it is reported by the Department of Mines[1] that recent discoveries in the Transvaal indicate a source from which an enormous supply of asbestos will soon be obtainable.

The total production of the Union of South Africa in 1918 was 3,674 short tons (3,333 metric), which, with 8,574 short tons (7,778 metric) produced by Rhodesia, makes a total of 12,248 short tons (11,111 metric) output for South Africa in 1918. In 1917 the total output was 15,782 short tons (14,317 metric), mainly crude fiber, much of which rivaled the Canadian.

Other countries.—In addition to the deposits of asbestos already noted, considerable deposits of asbestos have been reported and to some extent operated in Australia, Italy, Mongolia, New Zealand, Tasmania, the Philippine Islands, Cyprus, India, and Japan, but in general these countries afford but a small part of the asbestos of the world.

Mr. H. V. Snell, of Globe, Ariz., recently presented an extraordinary sample of pale-blue crocidolite from a new locality in South America. It is a remarkably long, soft, and fine silky fiber with high tensile strength. It has been examined by W. T. Schaller in the chemical laboratory of the United States Geological Survey and found to contain much iron and soda which, with its physical properties, show it to be crocidolite. The fibers are uniformly fine silky throughout a length of nearly 10 inches. They end abruptly as if cut off, but the terminations may be the sides or walls of a 10-inch cross-fiber vein. Similar large veins occur in South Africa. If South American crocidolite like the sample received occurs in such quantity as to be of commercial interest it will quickly attract the attention of asbestos producers and become a factor in the asbestos industry of America. Of course, such long fiber would have to be cut into about 3-inch lengths before it could be readily worked by the machines now in use.

TALC AND SOAPSTONE.

By J. S. Diller.

TALC.

PRODUCTION.

Talc is not a war mineral, but it was used for some definite war purposes and its production has increased somewhat over pre-war years.

The total sales of domestic talc in 1918 amounted to 191,477 short tons, valued at $2,089,960; those of 1917 amounted to 198,613 short tons, valued at $1,889,672. Therefore 7,136 short tons, or nearly 4 per cent, less domestic talc was sold in 1918 than in 1917, but because of the advance in price the value was $200,288, or about 11 per cent, greater.

Thirty-six producers of talc reported to the United States Geological Survey in 1918, of whom there were 8 in California, 6 in Vermont, 6 in North Carolina, 5 in Virginia, 3 in New York, 2 each in Georgia, Maryland, and Pennsylvania, and 1 each in Massachusetts and New Jersey.

Vermont ranked first in production, with a decreased output, the total sales being 90,537 short tons, valued at $775,012. New York, with a decreased output, ranked second in quantity and first in value, the total sales being 71,167 tons, valued at $902,100. California ranked third, with a total production of talc and soapstone of 11,864 tons in 1918. This was more than 2½ times the quantity of talc produced by California in 1917, besides a considerable quantity of soapstone. This decided advance in the production and utilization of talc, notwithstanding a slightly local decline in the average price on the Pacific coast, is one of the most important and significant features of the year in the development of the domestic talc industry.

Talc mined and sold in the United States in 1917 and 1918, by States.

State.	1917		1918		
	Quantity (short tons).	Value.	Quantity (short tons).	Value.	Average price per ton.
California	4,152	$74,000	10,364	$170,775	$16.48
New York	74,671	881,462	71,167	902,100	12.68
North Carolina	2,175	41,766	1,661	72,348	43.56
Vermont	93,960	625,150	90,537	775,012	8.56
Virginia	6,432	85,856	2,265	24,723	7.57
Georgia [a], Maryland, Massachusetts, New Jersey, Pennsylvania	17,223	181,438	14,483	145,002	10.01
	198,613	1,889,672	191,477	2,089,960	10.91

[a] The order of output of this group in 1918 is as follows: Pennsylvania, Maryland, Massachusetts, Georgia, New Jersey.

Talc mined and sold in the United States in 1917 and 1918, by classes.

Condition in which marketed.	1917		1918		
	Quantity (short tons).	Value.	Quantity (short tons).	Value.	Average price per ton.
Rough (crude)	12,269	$68,440	13,263	$106,228	$8.01
Manufactured into pencils and blanks [a]	5,781	176,404	945	114,002	120.64
Ground [b]	180,563	1,644,828	177,269	1,869,730	10.55
	198,613	1,889,672	191,477	2,089,960	10.91

[a] Includes slate pencils and metal workers' crayons and blanks used in making acetylene burners and other objects.

[b] For foundry facings, filler for paper, paint and rubber goods, toilet powder, foot ease, lubricators for dressing skins and leather, etc.

OCCURRENCE AND DISTRIBUTION.

Talc is an acid metasilicate of magnesium whose softness, greasy feel, and resistance to the action of heat and acid render it useful for many purposes. Another mineral, pyrophyllite, a hydrous silicate of alumina, resembles talc in some of its properties and is useful for the same purposes. It is mined and sold as talc at Glendon, Moore County, N. C.

Talc occurs in highly crystalline rocks, schists and gneisses, and generally results from the alteration of other magnesian minerals, such as pyroxene and hornblende. Its occurrence in commercial quantities is limited to ancient crystalline terranes. The finer qualities of talc are commonly associated with limestone and have been derived, as in New York and western North Carolina, from the alteration of tremolite schist in the limestone. The lenses of talc or tremolite schist usually stand on edge in the limestone and have to be mined by underground methods.

In North Carolina and Georgia the talc is associated with limestone, but in Harford County, Md., where the largest producing mine of fairly high grade talc is now in operation, the talc or soapstone, as it is often called, is an alteration product apparently of pyroxene in a large dike of basic igneous rock, probably pyroxenite or peridotite. Much of the rock is changed to serpentine [1] and finally to talc.

Of the great bulk of domestic talc marketed in the United States 95 per cent comes from nine States in the mountainous belt near the Atlantic coast, and about 5 per cent comes from California in the mountainous belt near the Pacific coast. In the broad stretch of 2,000 miles across the Mississippi Valley and the Great Basin there are at present no producing talc mines, although talc is known to occur and mines may yet be opened in the Rocky Mountains

PRINCIPAL USES.

The principal uses of powdered domestic talc are in the manufacture of paper and toilet powder, but the most valuable talc is that which is so uniformly fine grained that it can be readily cut and

[1] According to the Maryland Geological Survey's report on Cecil County, the large dike of serpentine that crosses Cecil County and Susquehanna River at Bald Friar enters Harford County and a mile west of Dublin contains the talc mined by the Harford County Talc Co.

bored in making gas tips and similar objects. The United States is well supplied with low and middle grades of talc suitable for paper but is deficient in high-grade material for toilet powder, pencils, and gas (lava) tips. Most of the domestic material of high grade comes from North Carolina and Georgia, but recently it has been mined also in California, Vermont, and Maryland.

IMPORTS.

About 4,440 tons, or 24 per cent, less talc was imported for consumption in 1918 than in 1917 and prices advanced everywhere. About 10 per cent of the imported talc was crude and the remainder ground. Of the imported talc 96 per cent came from Ontario, Canada. The remainder was chiefly high-grade material from Italy, but a small portion came from France.

Talc imported for consumption[a] in the United States in 1917 and 1918.[b]

Kind.	1917		1918		
	Quantity (short tons).	Value.	Quantity (short tons).	Value.	Average price per ton.
Crude and unground steatite and French chalk[c]	2,452	$10,710	1,434	$9,253	$6.45
Ground talc, or steatite, cut, powdered, washed, or pulverized[d]	16,157	258,787	12,735	251,323	19.73
	18,609	269,497	14,169	260,576	18.39

[a] General imports and imports for consumption for any period will differ to the extent that the value of entries for warehouse for the period differs from the value of withdrawals from warehouse for consumption. The term "entry for consumption" is the technical name of the import entry made at the customhouse and implies that the goods have been delivered into the custody of the importer and that the duties have been paid on the dutiable portion. Some of them may be afterwards exported.

TARIFF.

According to the present tariff, crude and unground talc enters free of duty, but on French chalk, ground, cut, powdered, washed, or pulverized talc, there is a duty of 15 per cent ad valorem.

A bill (H. R. 9063) was introduced September 5, 1919, by the chairman of the Ways and Means Committee of the House of Representatives, to increase the present duty on talc as follows: Talc, steatite, soapstone, and French chalk, crude and unground, ¼ cent per pound; when ground, washed, pulverized, or powdered, 1 cent per pound; when cut or sawed or in the form of blanks, crayons, or cubes, 2 cents per pound; and 50 per cent ad valorem on manufactures of talc, talcum, steatite, soapstone, and French chalk wholly or partly manufactured if not decorated; if decorated, 60 per cent ad valorem. An association of producers of talc and soapstone has recently been formed (August, 1919) in the United States (Freeland Jewett, of Boston, president, and R. B. Ladoo, of the Bureau of Mines, Washington, D. C., secretary) and one of its principal activities for the present will be the consideration of protective tariff measures.

WORLD'S PRODUCTION.

United States.—The world's production of talc for the last six years 1913–1918, inclusive, is shown concisely in the accompanying table. Of the total production probably less than 1 per cent was used in crude form and the remainder was ground. The large output of the United States (58 per cent of the world's production in 1918) is a matter of interest, but when we consider that in addition to its large production the United States imported more than 10 per cent of the total quantity of talc produced by all other countries combined and exported very little, it becomes strikingly evident that the United States is preeminently a consumer of talc. Of the world's production in 1918 the United States produced 58 per cent and consumed nearly 63 per cent, leaving approximately 37 per cent for consumption by the rest of the world.

France.—France ranks next to the United States in the production of talc, and the French talc is of excellent grade. The department of Ariège, near the north foot of the Pyrenees, furnishes more than four-fifths of the total output of France. The French chalk so widely known comes from southeastern France near Toulon, a port on the Mediterranean. The production of talc in France in 1913 was more than 66,000 short tons (60,175 metric tons). As the war advanced production and exportation decreased greatly. However, the resources and possible production have remained unimpaired, and there will be an output, apparently, of more than 60,000 tons annually when production has been fully resumed.

Italy.—The talc of Italy is highly prized for its purity and is imported chiefly for use in the manufacture of toilet powder, though some of it is so compact that it can be cut and used for gas tips. The principal region of production is in the Alps of northwestern Italy, west and southwest of Turin. Italy furnished about 8 per cent of the talc produced in 1918, and nearly 2 per cent of its output came to the United States.

Canada.—The only important center of production of talc in Canada is in Ontario, Hastings County, near Madoc, about 100 miles northeast of Toronto. Of the 18,190 short tons (16,502 metric tons) produced in 1918, having an average value of $6.20 per short ton, 67 per cent was imported into the United States at an average declared value of $17.57 per ton. Much of the talc was imported crude and ground in the United States, but a large part of it was ground in Canada. Much of it is used for paper, but it lacks the fibrous quality of the New York talc, though it is generally freer from grit.

Austria.—Statistics of the production of talc in Austria are not available for the years mentioned in the table, but the United States Department of Commerce reports exports of talc from Austria-Hungary in 1913 amounting to about 8,083 metric tons. If we assume that about half of the total output of talc in Austria is used in that country and the other half exported the total production in 1913 would have been about 16,000 metric tons. On account of the disturbed condition of the country the production in 1914 and later years fell off to not more than 12,000 metric tons. The chief producing center is in Styria, about 100 miles southwest of Vienna. Much talc is used in Austria in the manufacture of paper.

Norway.—The Province of Bergenlius, northeast of Bergen, Norway, produced about 12,000 metric tons of talc during the four years 1913–1916, inclusive, an average of about 3,000 tons annually.

Spain.—Spain has long been a moderate but variable producer of talc. Its chief source is on the southern slope of the Pyrenees, in the Province of Gerona, northeast of Barcelona. The average production for the last six years has been 3,386 metric tons, which agrees closely with the output in 1918 and shows that the industry has not been much influenced by the war.

Germany.—The talc of Germany comes chiefly from the Fichtel Gebirge in Bavaria, where the average production for seven years prior to the war was about 3,000 metric tons. Recent statistics are not available, but 3,000 tons may be assumed as a rather generous estimate of the output under the disturbed conditions of 1918.

India.—One of the most widely distributed minerals in India, according to the Geological survey of India, is steatite, either in the form of coarse potstone (soapstone), so called on account of its general use in making pots and dishes, or in the more compact form suitable for cutting. The production has greatly increased in the last few years, especially at Jubbulpore, in the central provinces, and at Meiktila, in Burma. The material imported into the United States from India is largely of the grade suitable for lava tips and similar objects and reaches this country chiefly through England.

British South Africa.—British South Africa is beginning to attract the general attention of talc users on account of the quality, variety, and abundance of talc which it contains, especially in the Transvaal and Rhodesia. Important production began in 1916, and the deposits promise to furnish another source for the higher grades of talc.

[a] Statistique de l'industrie minérale en France pour l'année 1913, p. 61. (Statistics from 1914 to 1917 not available. Average production for 1912 and 1913 given under 1918.)
[b] Rivista del Servizio minerario, 1917, p. 63. Not available for 1918, but the average crude for 1913–1917 is 23,951 tons.
[c] Canada Dept. Mines, Mines Branch, Ann. Repts., 1913–1918.
[d] Statistics for Austria not available for years mentioned in table. Department of Commerce reports talc exported from Austria-Hungary in 1913 as 80,828 metric quintals, or 8,083 metric tons. Much talc is used in Austria, especially for paper. If we assume that somewhat less than half of the total output is used in Austria, the total production in 1913 was about 16,000 tons. As talc is rather a peace mineral and war delayed production, the output in 1915–1918, inclusive, would probably average less than 12,000 metric tons annually, although the capacity of the mines apparently is greater.

SOAPSTONE.

PRODUCTION.

The name soapstone is correctly applied in the United States to a massive crystalline rock composed chiefly but not wholly of talc. The interlocking grains of talc and associated mineral matter bind the mass together. As talc is a soft mineral and easily broken, soapstone is a weak rock, and the loss by breakage in quarrying it, sawing it into slabs, making it into various objects, and transporting them to market is very great, roughly estimated at 90 per cent of the total quantity quarried.

Soapstone is usually quarried in large blocks, then sawed into slabs, and for the greater part manufactured into various objects in mills near the quarries before being marketed. The selling price ranged in 1918 from $10 to $40 a ton, and the average was about $35 a ton.

Virginia, with three large quarries, is by far the largest producer and manufacture of soapstone. California and Vermont have one producing plant each and together yield nearly one-tenth as much as Virginia. The total production of soapstone in the United States in 1918 was 16,830 short tons, valued at $591,059. No imports or exports of soapstone into or from the United States are reported.

OCCURRENCE.

The rock from which the soapstone in Virginia is obtained forms a large belt in an intrusive mass extending northeastward through Nelson, Albemarle, and Orange counties. This large intrusive mass

will afford an abundant supply for many years to come. It appears to have been derived from what was originally a basic igneous rock, probably pyroxenite or peridotite. The pyroxene and olivine in many places are altered to serpentine, and the alteration may finally result in the formation of talc. The hardest soapstone is only partly changed to talc and contains much residual pyroxene. It takes a dull polish which makes it more attractive for some purposes. In Maryland where similar rocks occur they are in places completely altered to talc so compact, fine grained, soft, and free from impurities that it can be readily carved, and in such places the rock should be called talc instead of soapstone.

WORLD'S PRODUCTION.

Soapstone is one of the rocks that was most widely useful to primitive man, who, on account of its softness, resistance to sudden changes of heat, and slow radiation, employed it chiefly for making pots; and it thus became generally known as potstone. Similar uses still exist in the soapstone stove, foot-warmer, and fireless cooker, although the principal application of soapstone, especially in this country, is in laundry tubs and laboratory tables, hoods, and tanks.

World's production of soapstone (as far as available), 1913–1918, in metric tons.

Country.	1913	1914	1915	1916	1917	1918
United States	24,097	19,240	18,647	17,828	18,357	15,268
United Kingdom	40	180	850	301	1,233	936

The commercial production of soapstone in the United Kingdom began about 1912 and is increasing. Part of the output comes from Scotland, but most of it from Ireland. France, Spain, and Germany are each represented as producing soapstone or steatite, but the product is reported with talc, and the proportion of each can not be readily ascertained.

CEMENT.

By Ernest F. Burchard.[1]

INTRODUCTION.

The marked decline in the output of cement in 1918, amounting to about 22 per cent, as compared with 1917, was the result of the continued curtailment begun in 1917 of building operations not essential to the war and of the continuation of the war restrictions imposed by the Government upon fuel supplies, transportation facilities, and labor. The output in 1918 was the lowest since 1909. On the other hand, wages and fuel costs continued to increase to such an extent that selling prices of cement were advanced greatly, that of Portland cement reaching an average of nearly $1.60 a barrel at the mills, the highest price in 20 years.

Statistics of the cement industry in 1918 were issued on January 21, 1919, by the United States Geological Survey in a press bulletin which gave estimates of shipments, prices, production, and stocks; and an advance statement of final figures of shipments, prices, production, stocks, exports, and imports was issued, also as a press bulletin, May 19, 1919, and was published in the "Preliminary report on the mineral resources of the United States," August 7, 1919, pages 32 and 33. The estimates of shipments exceeded the final figures by 1 per cent, those of production by 0.7 per cent, and those of stocks by 1.3 per cent.

This chapter includes a section on concrete ships in 1918, prepared by R. W. Lesley, of Philadelphia, Pa., associate member of the American Society of Civil Engineers, one of the pioneer manufacturers of Portland cement, and a member of the committee on concrete ships of the American Concrete Institute, in continuation of an article by him on the same subject in this chapter for 1917, and also a section on imports and exports of cement in foreign countries, furnished by R. S. Schultz, jr., recently works manager of the Marquette Cement Manufacturing Co., La Salle, Ill. These papers deal with subjects that are of present interest to the cement industry and to the public, and the writer desires to express herewith to the authors his appreciation of their courtesies.

THE CEMENT INDUSTRY IN RELATION TO THE WAR.

The course of cement manufacture during the last five years affords an illustration of the way in which an industry of vital importance to the Nation in war time can do its share and yet suffer depression as the result of conditions imposed by the war.

[1] The statistics of production of domestic cement were prepared by Mrs. H. L. Bennit, those showing imports into and exports from the United States were compiled by J. A. Dorsey, and those pertaining to foreign countries by R. S. Schultz, jr.

In an earlier bulletin[1] it was pointed out that the cement industry in the United States enjoys absolute independence of foreign supplies of raw materials or manufacturing machinery and that the United States produces more Portland cement than is consumed within the country. The raw materials are abundant and cheap, and manufacturing plants are well distributed throughout areas of notable consumption.

The military importance of cement can not be overestimated. It is used mostly as an ingredient in concrete, and concrete possesses great adaptability to a wide variety of uses. Besides being cheap, easily and quickly handled, sanitary, and durable, concrete is suitable for structures that are submerged as well as those in dry places, and all these characteristics taken together render it of great military importance. Among the military structures in which concrete is used are armories, barracks, roads, bridges, coast and interior fortifications, gun emplacements, trench linings, bombproof shelters, magazines for explosives, tunnels, retaining walls, sea walls, wharves, dry docks, water reservoirs, aqueducts, sewers, sewage-treatment works, incinerators, stables, floors, roofs, munition-factory buildings, warehouses, fuel-oil tanks, barges, ships, and structures in the interior of battleships.

CONDITIONS DURING THE WAR.

The year 1914 witnessed the first recorded decrease in annual production of Portland cement in the United States. The industry had experienced a remarkable growth during the preceding 10 years, and it was only natural that a slight check should come at this time. The average price per barrel in bulk at mills in 1914, 92.7 cents, represented a decrease of 7.8 cents from the average of 1913, and indeed the beginning of the war in Europe may be said to have marked a depression in the American cement industry from which only a temporary recovery was made during the whole period of the war.

The Portland cement industry showed no noteworthy development in 1915, notwithstanding the greater activity in the metal industries. In view of the experiences of 1914 manufacturers exercised considerable caution, the result of which was a slight increase in the volume of shipments, a small decrease in the quantity of cement manufactured, and a considerable decrease in the stocks of cement on hand, all indicating a correction of the tendency toward overproduction that had manifested itself at times during the preceding few years. The average price in 1915, 86 cents a barrel, represented a decrease of 6.7 cents a barrel below the price in 1914, and the estimated consumption of Portland cement per capita in the United States was 0.83 barrel, compared with 0.77 barrel in 1914. The total production in 1915 represented about 66 per cent of the apparent actual manufacturing capacity, according to figures reported to the Geological Survey.

In 1916 the conditions were more satisfactory. At the beginning of the year the industry was already feeling the effects of the gradual revival of activity in construction work, and throughout the year mills in all parts of the United States were busy manufacturing and shipping cement at a rate greater than at any other time since 1913, although labor troubles and lack of freight cars operated as a handicap.

[1] Burchard, E. F., Our mineral supplies—Portland cement: U. S. Geol. Survey Bull. 666-S, 1917.

Higher prices prevailed, averaging $1.103 a barrel at the mills, and six new plants reported their first production in 1916, one each in California, Minnesota, New York, Oklahoma, Oregon, and Texas. The plants in Oregon and Texas are close to tidewater. About 68 per cent of the cement-manufacturing capacity was employed during 1916.

As a result of increased business in 1916 stocks of Portland cement were reduced below the normal, yet the reserve of more than 8,250,000 barrels on hand at the beginning of 1917 proved to be sufficient for emergencies. The consumption of Portland cement per capita in 1916 was estimated at 0.89 barrel, the highest during the period of the war.

In 1917 the cement industry, in common with most other manufacturing industries, faced unusual conditions. The demand for cement was generally very good during the first five to eight months but showed a decided falling off during the remainder of the year. The strong demand in the early part of the year so greatly stimulated production that the quantity of finished cement of all kinds manufactured reached a total of more than 93,000,000 barrels—the largest production ever recorded, and yet only about 68 per cent of the manufacturing capacity was reported to have been employed. The total shipments, on the other hand, decreased, and the stocks increased accordingly. The consumption per capita in 1917 was estimated at 0.84 barrel. The average price of cement ($1.354) represented an increase of 25 cents over the average for 1916, and, although the net profits appear not to have been great, the effect of prices high enough to minimize the chances of loss and the absence of price cutting seem both to have stimulated production and to have encouraged the completion of three new mills and the resumption of operations at one mill that was idle in 1916.

The only step taken by the Government to insure an adequate supply of cement for military purposes and at the same time hold prices at fair figures was taken in cooperation with representatives of the cement industry in 1917, shortly after the entrance of the United States into the war, when the first scale of prices shown on page 581 was fixed. It was furthermore agreed that the Government requirements should be distributed as evenly as possible among the cement mills tributary to the localities where the cement was needed.

The adverse effects on the cement industry of the entrance of the United States into the European war began to be generally felt after the middle of the year and consisted mainly in shortage of fuel, railroad cars, and labor, and in the lessened demand for cement in some districts resulting from the curtailment of building operations not essential to the war. The necessary railroad embargoes were far-reaching; they affected supplies of fuel and other raw materials and of machinery and mill supplies and also shipments of cement to so great an extent that some mills had to be closed temporarily on account of lack of storage capacity.

In 1918, as has already been stated, the production of cement was the lowest since 1909. The average per capita consumption was 0.64 barrel in 1918 and the manufacturing capacity utilized was about 51 per cent of the total. The military requirements of the

Government, amounting to about 11,000,000 barrels, were easily met by the producers, the commercial business was subnormal on account of curtailment in construction work, and exports suffered through lack of ships. The average price per barrel ($1.596) represented nearly as large an increase as in 1917 and was the highest price realized in the last 20 years.

If the five years of the war are considered as a whole the average annual production and shipments of Portland cement each amounted to nearly 86,000,000 barrels—a quantity greater than the annual production of any year prior to 1913, but as compared with the average annual capacity of the mills for manufacturing cement during this period, which is conservatively estimated at about 130,000,000 barrels, it is seen that the cement industry was abnormally restrained. The lowest factory prices during the war were about 14 per cent less than the pre-war price of 1913, and the highest prices were nearly 59 per cent above the level of 1913. Wholesale market prices dropped correspondingly, but they also rose to greater excesses above the price of 1913, in some places recording advances of more than 110 per cent.

PRODUCTION OF HYDRAULIC CEMENTS.

The total quantity of Portland, natural, and puzzolan cements marketed or shipped from the mills in the United States in 1918 was 71,348,474 barrels, valued at $113,554,854, as compared with 91,342,930 barrels, valued at $123,210,458, in 1917—a decrease in quantity of 19,994,456 barrels, or 21.9 per cent, and a decrease in value of $9,655,604, or about 7.8 per cent.

Principal hydraulic cements shipped from factories in the United States in 1916, 1917, and 1918.

Class.	1916		1917		1918	
	Quantity (barrels).	Value.	Quantity (barrels).	Value.	Quantity (barrels).	Value.
Portland	94,552,296	$104,258,216	90,703,474	$122,775,088	70,915,508	$113,153,513
Natural Puzzolan	842,137	430,874	639,456	435,370	432,966	401,341
	95,394,433	104,689,090	91,342,930	123,210,458	71,348,474	113,554,854

The historical table that follows gives the production and value of natural, Portland, and puzzolan cements so far as recorded by the Geological Survey. The curves in figure 66 show graphically some of these data from 1890 to 1918. The figures in the table represent actual production of Portland cement for all years and of natural and puzzolan cements until 1911, inclusive, after which the figures for these cements represent shipments. In 1916, 1917, and 1918 there was but one manufacturer of puzzolan cement; hence the shipments of puzzolan are included with those of natural cement. No figures for production or stocks are collected for natural and puzzolan cements because production and shipments are generally nearly the same and stocks are relatively small.

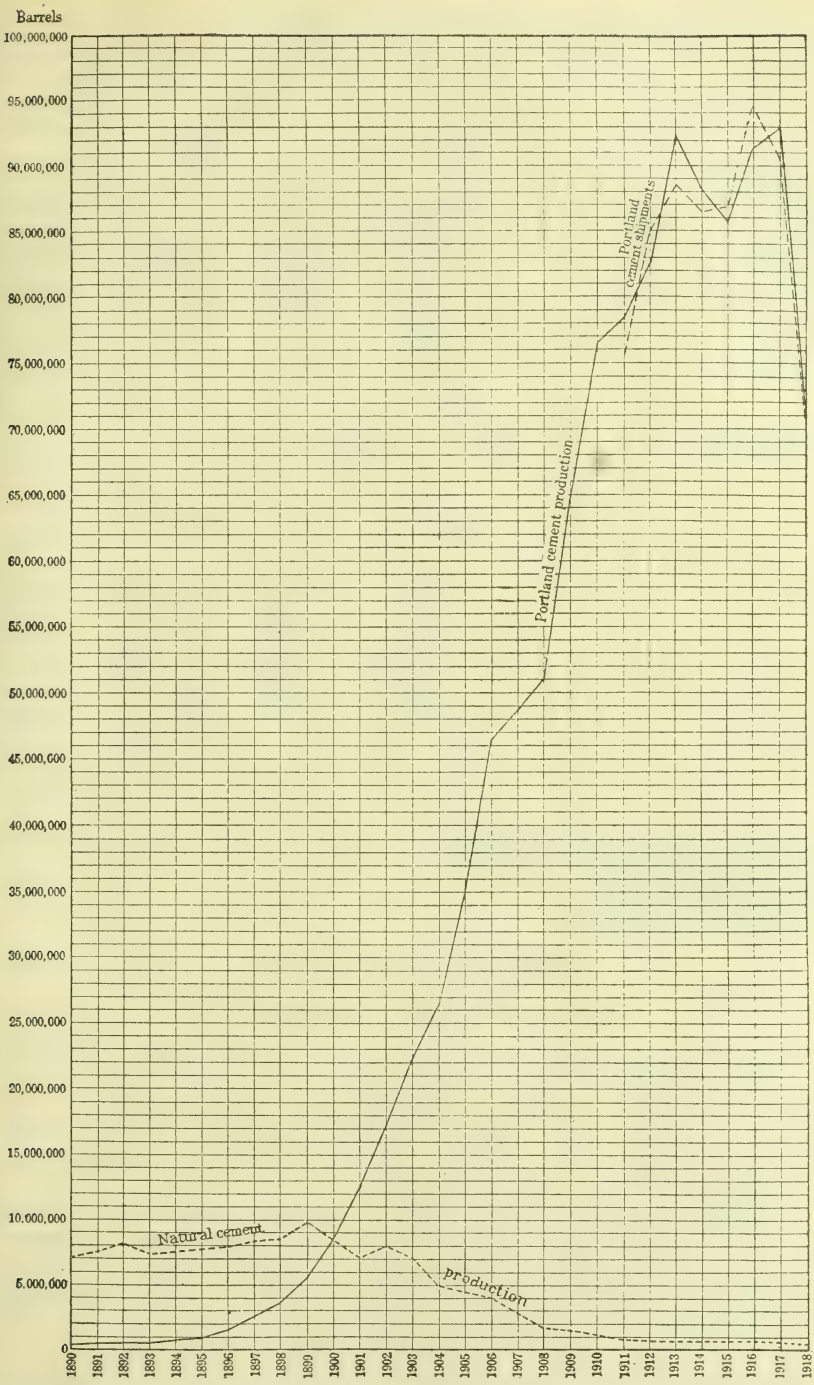

FIGURE 66.—Production of Portland and natural cements, 1890–1918, and shipments of Portland cement, 1911–1918.

Principal hydraulic cements produced in the United States, 1818–1918.[a]

PORTLAND CEMENT.

PRODUCTION AND SHIPMENTS.

The total production of Portland cement in the United States in 1918, as reported to the United States Geological Survey, was 71,081,663 barrels, valued at $113,446,334. This represents a decrease in quantity of 23.4 per cent and in value of about 9.7 per cent. The value assigned is computed at $1.596 a barrel, the average price of the Portland cement shipped in 1918.

The shipments of Portland cement from the mills in the United States in 1918 were, according to reports received by the Geological Survey, 70,915,508 barrels, valued in bulk at the mills at $113,153,513, compared with 90,703,474 barrels, valued at $122,775,088, in 1917—a decrease in quantity of 19,787,966 barrels, or 21.8 per cent, and a decrease in value of $9,621,575, or about 7.8 per cent.

The average price per barrel for the whole country in 1918, according to these figures, was $1.596, compared with $1.354 in 1917—an increase of 24.2 cents a barrel, or 17.9 per cent. This represents the

selling price of cement in bulk at the mills and includes cost of labor and packing but not the value of the sacks or barrels. The average price per barrel for the country was 8.5 cents higher than the average price received for Portland cement in Pennsylvania, where it was lowest, and was near the average price received in Illinois, Indiana, Missouri, New York, and the following districts: Lehigh, Kentucky-southern Indiana, Ohio-western Pennsylvania, Maryland-Virginia-West Virginia, and Iowa-Minnesota-Missouri. It was 29.8 cents below the average received in Washington, where Portland cement brought the highest price of the year ($1.894). The average prices for State and district were nearer the general average price for the country in 1918 than in 1917. The quantity of Portland cement made in 1918 (71,081,663 barrels of 376 pounds) was approximately equivalent to 11,931,565 long tons, and the price per ton was about $9.51.

The average price of Portland cement in the United States is slightly above the average for ordinary gray cement on account of the inclusion in the total shipments of a small quantity of white Portland cement. This white cement was produced in the Lehigh district, so that the value for that district has been increased in greater proportion than that of the other districts. Two mills, both in Pennsylvania, reported the production of white Portland cement in 1918.

At the beginning of 1918 the rate of shipments of Portland cement from the mills was about 2,300,000 barrels a month, the lowest for the year. From January to April there was an increase to more than 8,500,000 barrels, followed by a slight decline in May and a recovery in June; then by a drop to about 7,000,000 barrels in July, and then by a slight rise in August, and, finally by a steady and rapid decline to less than 3,000,000 barrels in December. Production showed less fluctuation, beginning at about 3,300,000 barrels, reaching a maximum of nearly 8,000,000 barrels in June, and declining to about 4,200,000 barrels in December. The average monthly shipments and production in 1918 were, respectively, about 5,910,000 barrels and 5,923,000 barrels, compared with about 7,559,000 barrels and 7,735,000 barrels, respectively, in 1917. Stocks of finished cement in 1918 were highest in February, when they totaled about 12,250,000 barrels, and lowest in June and October, when they were less than 8,000,000 barrels, whereas at the beginning and end of the year they were about 10,350,000 barrels and 10,450,000 barrels, respectively.

PRODUCTION AND SHIPMENTS, BY STATES.

In the following table the production and shipments and the corresponding values of Portland cement for 1917 and 1918 are arranged by States in alphabetic order, provided there are three or more producers or shippers in a single State, or permission is given to publish figures where there are less than three. By the term "producer" is meant a Portland-cement manufacturing company, whether the company operates one or more plants. In the table the term "producing plant" is applied to a mill or group of mills located at one place and operated by one company, but each establishment at a different place is counted as a plant. There were producing plants in 27 States in 1917 and 26 States in 1918, but as a number of these States

did not contain three or more plants it has been necessary to group together in this table several States that are not closely related geographically. This disadvantage is, however, compensated for in the table "Portland cement produced and shipped by districts," in which statistics are given for groups of States—generally not more than three—that are geographically related.

In all the States in which Portland cement was manufactured in 1918 there were decreases in both shipments and production as compared with the output in 1917, but the average factory price per barrel showed an increase in all the States. The net change for the whole country was a decrease in shipments of 19,787,966 barrels, or 21.8 per cent, and a decrease in production of 21,732,539 barrels, or 23.4 per cent. In 1918 production exceeded shipments by 166,155 barrels.

Portland cement produced and shipped in 1917 and 1918, by States.

PRODUCTION AND SHIPMENTS, BY COMMERCIAL DISTRICTS.

The division of the cement-producing territory into 12 geographic units, termed "commercial districts," is based to some extent on the relations of the Portland-cement plants to their trade territory.

These relations are, of course, governed largely by transportation facilities and rates, and in forming the districts it has been found advisable to divide Pennsylvania, Indiana, and Texas in order to group the plants commercially.

As shown in the accompanying table there were decreases in both shipments and production in all districts in 1918 as compared with the output of each in 1917, but the average factory price per barrel showed a general increase.

Portland cement produced and shipped in 1917 and 1918, by districts.

LEHIGH DISTRICT.

The production of Portland cement in the Lehigh district, in eastern Pennsylvania and western New Jersey, in 1918 was 19,701,820 barrels, compared with 24,423,507 barrels in 1917—a decrease of 4,721,687 barrels, or 19.3 per cent. The shipments from mills in this district in 1918 amounted to 19,351,123 barrels, compared with

24,423,641 barrels in 1917—a decrease of 5,072,518 barrels, or 20.8 per cent. (See fig. 67.) The total value of the Portland cement shipped from this district in 1918 was reported as $29,399,457, at an average price of $1.519 a barrel in bulk at the mills, as compared with $29,787,313, or $1.220 a barrel, in 1917. The production of white Portland cement from two plants in this district is included in the figures for 1918. As the average price reported for the white cement was considerably higher than that reported for ordinary gray cement,

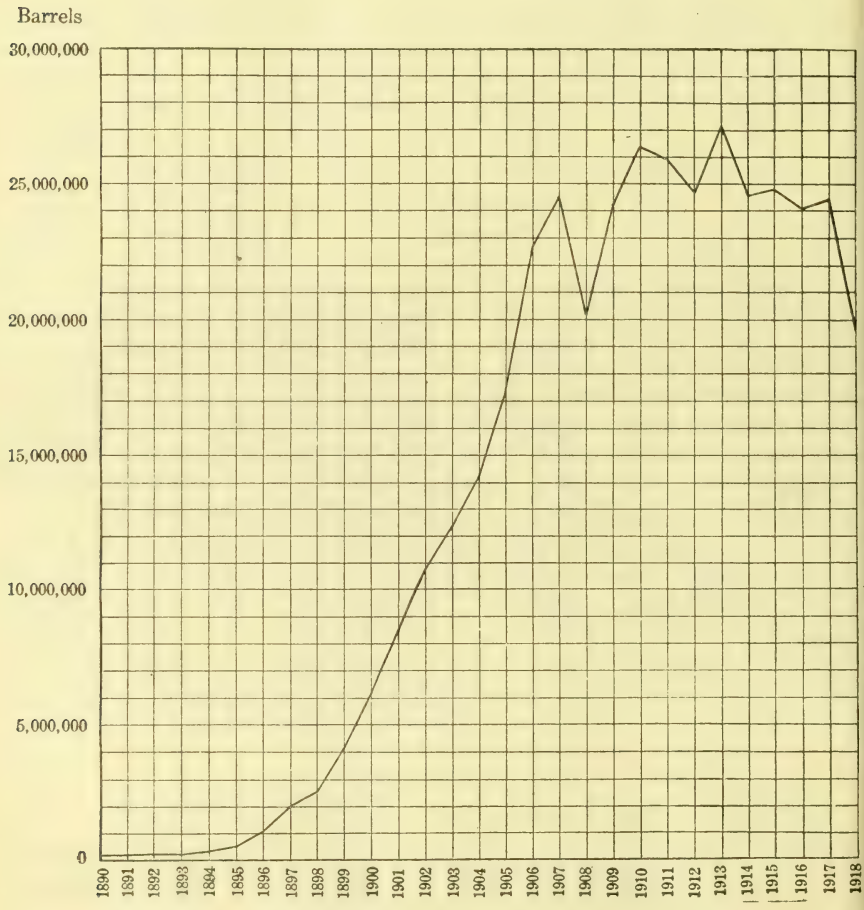

FIGURE 67.—Production of Portland cement in the Lehigh district, 1890–1918.

the average price for the district is slightly higher than if it represented gray Portland cement alone.

Twenty plants produced and shipped Portland cement from the Lehigh district in 1918, as compared with 20 producers and 21 shippers in 1917.

The Lehigh district produced 27.7 per cent of the total output of Portland cement in the United States in 1918. In 1897 this district produced 74.8 per cent of the total for the United States.

Portland cement produced in the Lehigh district and in the United States, 1890–1918.

STOCKS AT MILLS.

The stock of Portland cement reported on hand at the various mills at the end of 1918 amounted to 10,453,950 barrels, compared with 10,353,838 barrels on hand at the end of 1917—an increase in stock of 100,112 barrels, or 1 per cent, during 1918. The reports of stocks at a few mills in 1917 were revised by the producers, at the request of the Geological Survey, and the stock reported for 1918 checks with the revised total for 1917 within 0.63 per cent of the stock calculated by balancing the shipments for 1918 against the production of 1918, plus the stock at the close of 1917. This agreement is sufficiently close, considering that the volume of stocks can not be measured with great accuracy.

Portland cement in stock Dec. 31, 1917, and Dec. 31, 1918, by States.

State.	Quantity (barrels).		Percentage of change in 1918.

1914	12,773,463	1918	10,453,950

DOMESTIC CONSUMPTION OF PORTLAND CEMENT.

An estimate of the total consumption of Portland cement in the United States may be made by adding the imports to the shipments and subtracting the exports from the sum. Of course, a variable but considerable stock of cement is at all times in transit, in warehouses at distributing points, and awaiting use on the ground at large jobs, so that the estimate thus made is at best approximate. Still another uncertain element in this estimate is the fact that as imports and exports are classed as hydraulic cement the records do not discriminate between Portland and other cements. Portland cement, however, constitutes by far the greater part of the exports, and, as the tables show, the imports are small. The apparent domestic consumption in 1918 amounted to 68,663,367 barrels, compared with 88,119,582 barrels in 1917, a decrease of 19,456,215 barrels or about 22 per cent, as compared with a decrease of 4 per cent in 1917.

The following table gives the figures necessary for estimates of consumption so far as available, as prior to 1911 no records are at hand for stocks:

Apparent domestic consumption of Portland cement, 1911–1918, in barrels.

Year.	Shipments.	Imports.	Exports.	Apparent consumption.
1911	75,547,829	164,670	3,135,409	72,577,090
1912	85,012,556	68,503	4,215,532	80,865,527
1913	88,689,377	85,470	2,964,358	85,810,489

1917	90,703,474	2,323	2,586,215	88,119,582
1918	70,915,508	305	2,252,446	68,663,367

PORTLAND CEMENT CONSUMED PER CAPITA.

In estimating the consumption of Portland cement in the States and the dependencies of the United States, the consumption by political divisions is, of course, not absolute, as it is represented only by the records of shipments by manufacturers into the several States. Also, the shipments of cement into a State do not equal the consumption in that State during the same period, but if taken for a long period they should afford a very fair index to that consumption.[1] The consumption in the outlying possessions of the United States is represented simply by the official statistics of exports to those countries from the United States and do not include small imports that may have come from foreign countries. The table of exports to other countries on page 587 shows the shipments of cement from the United States to the Philippines, but there are no data available as to the imports of cement to the islands from foreign countries, which of course, should figure in their per capita consumption. The simplest available common index appears to be the estimated consumption per capita in barrels, which has been obtained by comparing the shipments into States and possessions with the population for the States and possessions in 1917 and 1918, as estimated by the Bureau of the Census.

There is a discrepancy between the official figures of the Bureau of Foreign and Domestic Commerce for exports of cement, given on page 587, and the exports reported by manufacturers, as given in the following table, owing to the fact that cement shipped from mills destined for foreign countries is reported by the shipper as exported, whether or not it leaves the country during that calendar year, but the Bureau of Foreign and Domestic Commerce bases its export figures on the cement that actually leaves the country, according to its records. The exports given by that bureau include all natural or puzzolan cement which may have been exported, whereas the table of per capita consumption given below relates only to Portland cement. Another source of apparent disagreement is the fact that the lump figure for unspecified exports reported by manufacturers does not include the exports to Alaska, Hawaii, and Porto Rico, statistics for which are given separately in the same table.

The per capita consumption shown by the table necessarily falls short of the total apparent consumption by the quantity of the imports. These, however, are small—only 2,323 barrels in 1917 and 305 barrels in 1918.

The highest per capita consumption in 1918 was that of the District of Columbia, 1.61 barrels. The next seven divisions in which the per capita consumption was more than 1 barrel were Delaware (1.24), California (1.16), Arizona (1.09), Maryland (1.05), Michigan (1.04), Iowa (1.03), and Wyoming (1.02). In 1917 Montana showed the highest per capita consumption, 1.69 barrels. Nineteen States in 1917 exceeded a per capita consumption of 1 barrel, and 17 States in 1916. Of the 8 States that consumed more than 1 barrel of Portland cement per capita in 1918, 4 were west of Mississippi River, compared with 10 in 1917. Comparison of the figures by States shows that all of the 52 divisions showed some change in per capita consumption, 8 having shown an increase and 44 a decrease. The increases were moderate, the most noteworthy having been in Virginia,

[1] Data on per capita consumption of Portland cement by States beginning with the year 1914 are available in preceding volumes of Mineral Resources.

from 0.61 to 0.93 barrels; Delaware, from 0.99 to 1.24; and the District of Columbia, from 1.38 to 1.61. The general average per capita consumption was 0.64 barrel in 1918, compared with 0.84 barrel in 1917.

Estimated per capita consumption of Portland cement in the United States and outlying possessions in 1917 and 1918.

In connection with the study of consumption of cement it is of interest to compare the shipments from the mills within a State or group of States with the estimated cement consumption of that area

and thus to ascertain the extent of the surplus or deficiency in the supply of cement locally available. The following table has therefore been arranged with that in view. (Data for 1916 will be found in the chapter in Mineral Resources on cement in 1917.) The second table shows how much of the surplus product was consumed by each of the non cement-producing States and dependencies.

Estimated surplus or deficiency in local supply of Portland cement in cement-producing States, 1917–18, in barrels.

Consumption in cement-producing States	73,098,228	56,873,200
Total shipments	90,703,474	70,915,508

Among the cement-producing States or groups of States there are, of course, fewer deficiencies than surpluses, and certain of the deficiencies indicated are due to local conditions. For instance, in 1918 Illinois showed a deficiency of more than 1,200,000 barrels, while Indiana showed a surplus of more than 3,798,000 barrels. This is equalized in large part by the flow of cement from northeastern Indiana into the adjacent populous Chicago district in Illinois. Ohio showed a deficiency of about 3,720,000 barrels, which was largely supplied from Pennsylvania's surplus of more than 15,500,000 barrels. New York State, though a large producer, has a large deficiency, which is mostly supplied from the Lehigh district. The Iowa-Minnesota-Nebraska group showed a deficiency of more than 1,300,000 barrels in 1918, but the deficiency has rapidly decreased in the last few years, indicating that it will soon be overtaken by local production. The quantities consumed in the nonproducing States and dependencies are of interest in comparison with the other data. More than 500,000 barrels were consumed in 1918 in the District of Columbia and in each of the States of Connecticut, Louisiana, North Carolina, and South Carolina; and Massachusetts and Wisconsin each consumed more than 2,000,000 barrels; but the per capita consumption in all these States is a better index to the relative consumption than the total figures. The quantity consumed in the nonproducing States plus the unspecified quantities and the exports amounted in 1918 to 14,042,308 barrels, compared with 17,605,246 barrels in 1917, and in 1918 this total represented 19.8 per cent of the total shipments from mills in the United States.

PRICES.

Average prices of Portland cement sold in bulk at the factories as reported to the Geological Survey are shown in the tables of shipments by States and districts during 1917 and 1918, pages 572–573. According to these figures the average prices in 1918 ranged between $1.511 a barrel in Pennsylvania and $1.894 a barrel in Washington, as compared with $1.22 cents in the Lehigh district and $1.69 in Washington in 1917. The general average price for the whole country was $1.596 in 1918, compared with $1.354 in 1917, an increase of 24.2 cents per barrel, or 17.9 per cent. This is the highest average price that has been realized since 1898. The States whose increases were more than 25 cents per barrel were California, 36 cents; Michigan, 26 cents; New York, 31 cents; Oklahoma, 29 cents; Pennsylvania, 26.5 cents. All the districts, as well as every State, showed an increase in average price. The district average prices are, of course, nearer the general average than the State average prices.

The following prices on Portland cement at certain shipping points were quoted to the United States Government by the cement industry in 1917 and 1918. These prices were based on the understanding that the Government requirements would be small—less than 5 per cent of the total output—and that the price to the Government should not control the price to the trade. It was deemed possible to make these prices to the Government because of the fact that the burden, admittedly small, would also be evenly distributed, so that when the quota of the mills in a locality had been supplied any additional cement would have to be shipped from the nearest locality whose quota

had not been exhausted, and the price would then be the base price of the shipping locality plus the freight to the point of delivery.

The following prices per barrel exclusive of packages were accepted by the War Industries Board:

Prices of Portland cement to the United States Government at different shipping points, 1917 and 1918.

The cement prices established for the last four months of 1918 are apparently a downward revision of 3 cents a barrel from the former prices, but the new prices were for cement without bin inspection. A charge of 3 cents, however, was allowed for bin inspection, and as most purchasers required inspection to be made, there was practically no change in cement prices.

Figure 68 illustrates graphically the rapid early decline and the recent fluctuations in the general average factory prices of Portland cement, and the following table summarizes the same data:

Average factory price per barrel in bulk of Portland cement, 1870–1918.

1870–1880	$3.00	1895	$1.60	1907	$1.11
1881	2.50	1896	1.57	1908	.85

MARKET PRICES.

An interesting compilation of wholesale prices of cement by months, quarters, and years, 1913–1918, for various portions of the United States has recently been published by the War Industries

Board.[1] Where the prices quoted can be compared directly with those reported to the Geological Survey from the mills in a given State it is found that there is no great difference in yearly averages.

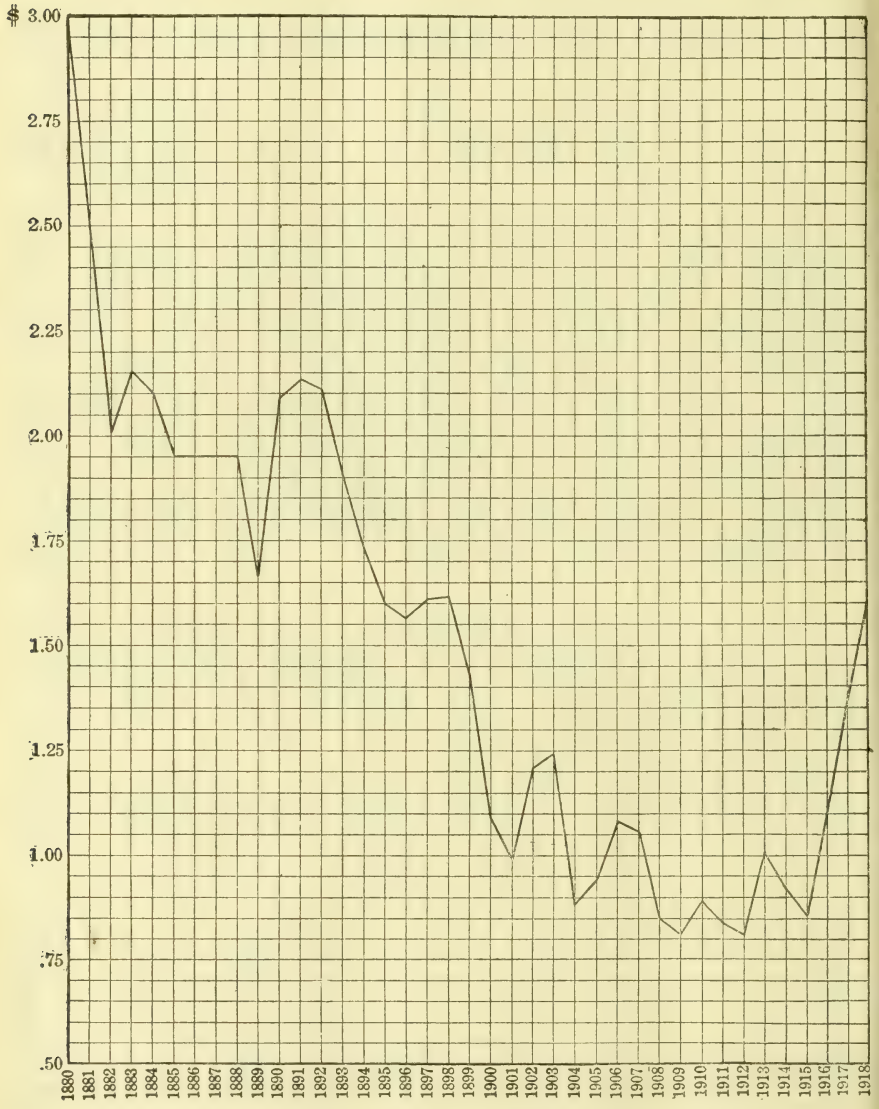

FIGURE 68.—Range in average factory price per barrel of Portland cement, 1880–1918.

Wholesale prices at the end of the war, however, had reached much higher figures than the factory prices. Cement prices are shown on a chart to have risen from a basis of 100 in 1913–14 to about 175 at the signing of the armistice in 1918, as compared with a maximum of

[1] Prices of cement: War Industries Board Price Bull. 41, pp. 8–9, 1919.

more than 200 for "all commodities." The price of cement is also stated not to have risen so rapidly as the prices of other building materials.

MANUFACTURING CONDITIONS.

PLANTS.

Portland cement was manufactured at 114 plants and shipments were made from 115 plants in 1918, as compared with 117 producing plants and 118 shipping plants in 1917—a net decrease of 3 producing and 3 shipping plants.

Six plants manufactured no cement during the year—one each in California, Kansas, Michigan, Nebraska, New Jersey, and New York, but the idle plant in California shipped cement from stock. One plant in New Jersey that shipped only from stock in 1917 resumed production in 1918. Two new plants produced Portland cement in 1918—the Old Mission, at San Juan de Bautista, Calif., and the Three Forks, at Hanover, Mont.

The new plants that began operations are equipped as follows:

Old Mission Portland Cement Co., plant at San Juan, Benito County, Calif. Wet process; limestone, clay, and shale; clinker burned with oil; four 8-by-150-foot kilns; daily clinker capacity, 2,000 barrels.

Three Forks Portland Cement Co., plant at Hanover, Fergus County, Mont. Wet process; limestone; clinker burned with coal; one 9-by-200-foot kiln; daily clinker capacity, 1,000 barrels.

KILNS.

The total number of rotary kilns reported in plants that operated in 1918 was 749, compared with 789 in 1917—a net decrease of 40 kilns. The number of active small kilns, 40 to 60 feet long, was decreased by 31; kilns between 60 and 100 feet long decreased by 4; 100-foot kilns increased by 21; 110-foot kilns decreased by 18; kilns 120 feet long remained the same in number; kilns 125 feet long decreased by 11; kilns 125 to 140 feet long decreased by 11; and kilns 150 feet or more in length increased by 5. The increase in the larger kilns is the natural trend in a period in which prevailed high manufacturing costs, together with a subnormal demand.

Lengths of rotary cement kilns in active plants in the United States, 1915–1918.

Length (feet).	Number of kilns.				Length (feet).	Number of kilns.			
	1915	1916	1917	1918		1915	1916	1917	1918

KILN FUELS.

A summary of kiln fuels reported in 1918 shows that 93 plants, employing 605 kilns, burned powdered coal; that 16 plants, employing 99 kilns, burned crude oil. At certain plants more than one

fuel is used. For instance, 2 plants reported coal and oil; 1 plant, coal and gas; and 2 plants, oil, coal, and gas. The percentage of cement burned by coal increased slightly.

Summary of Portland cement kiln fuels in 1917 and 1918.

Fuel.	1917				1918			
	Number of plants.	Number of kilns.	Barrels of cement.	Percentage of total.	Number of plants.	Number of kilns.	Barrels of cement.	Percentage of total.
Coal	93	636	76,410,379	82.2	93	605	58,605,244	82.4
Coal and crude oil	1	24	6,492,713	7.0	2	28	5,188,915	7.3

Natural gas	1	6						
	117	789	92,814,202	100.0	114	749	71,081,663	100.0

CAPACITY.

The total annual kiln capacity in the United States in 1918 of all the plants, either active or only temporarily closed, according to manufacturers' reports, was approximately 138,400,000 barrels of Portland cement, compared with about 136,750,000 barrels in 1917—an increase of 1,650,000 barrels, or 1.2 per cent. According to these figures the total production of cement in 1918 (71,081,663 barrels) was about 51 per cent of the total capacity, whereas the production in 1917 represented about 68 per cent of the apparent total capacity in that year.

Based on the reported kiln capacities, the following table of estimated capacities by districts has been prepared, and these figures, compared with the respective figures of production, give the apparent percentage of capacity utilized in 1917 and 1918.

Annual Portland cement manufacturing capacity of the United States, by commercial districts, 1917 and 1918.

District.	Estimated capacity (barrels).		Per cent of capacity utilized.	
	1917	1918	1917	1918
Lehigh district (eastern Pennsylvania and western New Jersey)	37,016,132	36,904,000	66.0	53.4
New York	8,552,480	8,411,400	63.3	48.7
Ohio and western Pennsylvania	9,379,040	12,983,000	78.3	49.6
Michigan and northeastern Indiana	8,672,400	7,770,000	60.7	52.9
Southern Indiana and Kentucky	4,836,200	4,550,000	58.1	35.4
Illinois and northwestern Indiana	13,859,780	14,060,000	78.8	51.0
Maryland, Virginia, and West Virginia	4,384,380	4,322,200	71.2	52.7
Tennessee, Alabama, and Georgia	4,657,400	4,500,000	78.9	66.5
Iowa, Missouri, and Minnesota	13,764,480	14,040,000	85.5	67.5
Nebraska,[a] Kansas, Oklahoma, and central Texas	12,197,570	10,579,500	63.2	50.8
Rocky Mountain States (Colorado, Utah, Montana, and western Texas)	4,336,200	4,498,000	75.2	50.9
Pacific Coast States (California, Washington, and Oregon)	15,594,260	15,783,100	47.3	35.2
	136,750,322	138,401,200	67.9	51.3

[a] Nebraska had no output in 1918.

RECOVERY OF POTASH.

The production of potash salts as a by-product of the manufacture of Portland cement continued during 1918 to be a subject of interest to the cement industry in view of the shortage in potash and the military needs for it. At the end of 1918 the production of potash salts was reported by 12 cement plants—3 of them in California, 1 in Indiana, 1 in Maryland, 1 in Michigan, 1 in New York, 3 in Pennsylvania, and 2 in Utah. At the same time 4 plants reported the construction of apparatus for the recovery of potash under way, and 13 plants reported that this recovery was under consideration. In 1917 there were 7 plants producing potash salts and about the same number reported apparatus under construction. In 1918 the quantity of potash (K_2O) produced by cement plants was 1,549 short tons, valued at $603,617—a slight decrease in quantity as compared with the output in 1917.[1]

Recovery of potash at Portland cement plants in the United States in 1918.

Plant and location.	In operation.	Under construction.	Under consideration.	Type of process.
California Portland Cement Co., Colton, Calif.	Yes			Leaching and evaporation.
Golden State Portland Cement Co., Oro Grande, Calif.		Yes

Portland Cement Co. of Utah, Salt Lake City, Utah.	Yes			Dry and wet precipitation.

NATURAL AND PUZZOLAN CEMENTS.

In 1917 and 1918 only one manufacturer reported an output of puzzolan or slag-lime cement, and in order that this quantity may be included in the cement totals for the United States without revealing confidential information it is added to the statistics of natural cement. The puzzolan cement plant is at Birmingham, Ala.

[1] For production of potash salts see the chapter on potash in Mineral Resources for 1918.

The natural cement and puzzolan cement in the United States marketed during 1918 amounted to 432,966 barrels, valued at $401,341, as compared with an output of 639,456 barrels, valued at $435,370, in 1917, a decrease in 1918 of 206,490 barrels, or 32 per cent, in quantity and a decrease of $34,029, or 7.8 per cent, in value. The average price of these cements per barrel at the mills in 1918 was 92.7 cents, as compared with 68.1 cents in 1917. It is of interest to compare these prices with those of Portland cement in 1917 and 1918, which were, respectively, $1.354 and $1.596.

Natural cement was produced in 1917 in nine plants, distributed in six States—at Binnewater (near Rosendale), Jamesville, and Fayetteville, N. Y.; Siegfried, Pa.; Speeds, Ind.; Utica, Ill.; Fort Scott, Kans., and Austin and Mankato, Minn. In 1918 the plants at Fayetteville and Jamesville, N. Y., discontinued operations, and a plant at Lisbon, Ohio, resumed activity, making eight active plants in 1918.

Natural and puzzolan cement shipped, 1917 and 1918.

FOREIGN TRADE IN CEMENT.

EXPORTS.

In 1918 the total quantity of hydraulic cement exported to foreign countries, including the Philippines and the Panama Canal Zone, was 2,252,446 barrels, most of it Portland cement, valued at $5,912,166 at the United States ports of shipment, or an average of approximately $2.62 a barrel, as compared with 2,586,215 barrels, valued at $5,328,536, or about $2.06 a barrel, in 1917. This represents a decrease in quantity of about 13 per cent, but an increase in value of nearly 11 per cent. The quantity exported in 1918 was about 3 per cent of the total production of hydraulic cement in that year.

The exports, as shown in the following table, go mainly to South America, which received more than 910,000 barrels, the West Indies, which received about the same quantity, and Central America, including Mexico, to which were sent more than 360,000 barrels, leaving only about 60,000 barrels for Europe, Africa, Asia, and Oceania. The export trade with the various countries fluctuates from year to year, the noteworthy increases in 1918 having been in exports to Argentina, British Guiana, Chile, and Peru, and the principal decreases in exports to Brazil, Cuba, the Dutch East Indies, Haiti, Panama, and Salvador.

Hydraulic cement exported from the United States in 1917 and 1918.[a]

[a] Statistics compiled from records of Bureau of Foreign and Domestic Commerce, Department of Commerce.

The following table gives the quantity and value of all classes of hydraulic cement exported during the years 1900–1918, inclusive, and the proportion of exports to the total quantity of hydraulic cement manufactured in the United States. The exports at present consist almost wholly of Portland cement.

Hydraulic cement exported from the United States, 1900–1918.[a]

Year.	Quantity (barrels).	Value.	Percentage of total quantity.	Year.	Quantity (barrels).	Value.	Percentage of total quantity.
1900	100,400	$225,306	0.6	1910	2,475,957	$3,477,981	3.2

IMPORTS.

The following table shows the quantities of foreign cement imported for consumption into the United States during the years 1878 to 1918, inclusive. The quantities given include all kinds of hydraulic cement.

The imports in 1918 were approximately 305 barrels of 380 pounds, valued at $1,200, or about $3.93 a barrel, as compared with 2,323 barrels, valued at $6,076, or about $2.62 a barrel, in 1917.

The table shows a decline in the imports of foreign cement for the six years ending with 1912, slight increases in 1913 and 1914, and large decreases since 1914, owing to the cessation of imports from Belgium, Germany, and France.

Foreign cement imported for consumption, 1878–1918, in barrels of 380 pounds.[1]

1878	92,000	1892	2,440,654	1906	2,273,493

1891	2,988,313	1905	896,845		

PORTLAND CEMENT IN CANADA.

The following statement is quoted from the preliminary report on the mineral production of Canada in 1918, issued by the Canada Department of Mines, Mines Branch, February, 1919. The statement of imports shows a smaller quantity than United States records show to have been exported to Canada from this country.

The total quantity of cement sold from Canadian cement mills in 1918 was 3,591,481 barrels, valued at $7,076,503, or an average of $1.97 a barrel, as compared with sales in 1917 of 4,768,488 barrels,

[1] Statistics compiled from records of Bureau of Foreign and Domestic Commerce, Department of Commerce.

valued at $7,724,246, or an average of $1.62 a barrel, showing a decrease in quantity sold of 1,177,007 barrels, or 24.68 per cent, and a decrease in total value of $647,743, or 8.38 per cent.

Sales of cement from mills in Quebec in 1918 were 1,564,360 barrels, valued at $3,003,571; in Ontario 1,220,003 barrels, valued at $1,976,815; and from Manitoba, Alberta, and British Columbia 807,118 barrels, valued at $2,096,117.

The total quantity of cement made in Canada in 1918 was 3,417,660 barrels, as compared with 4,987,255 barrels made in 1917, a decrease of 1,569,595 barrels, or 31.47 per cent.

Stocks of cement on hand January 1, 1918, were 1,660,406 barrels; at the end of December they had been reduced to 1,480,565 barrels.

The total imports of cement in 1918 were 20,695 hundredweight, equivalent to 5,913 barrels of 350 pounds each, valued at $19,851, or an average of $3.36 a barrel, as compared with imports of 8,580 barrels, valued at $19,646, or an average of $2.29 a barrel in 1917.

The total consumption of cement therefore, a small export neglected, was 3,603,414 barrels, as compared with a consumption of 4,777,068 barrels in 1917, a decrease in 1918 of 1,173,654 barrels, or 24.57 per cent.

IMPORTS AND EXPORTS OF CEMENT IN FOREIGN COUNTRIES.

By Robert S. Schultz, Jr.

SOURCES OF THE DATA.

The collection of data on exports and imports of hydraulic cements was undertaken by the War Trade Board, at Washington, D. C., just prior to the signing of the armistice in November, 1918. The data were particularly desired for use in connection with post-war conditions, with special reference to probable exports to South American countries. Undertaken originally with a field limited to South America, the work was expanded after the signing of the armistice to include all data available in Washington at that time on cement imports and exports in all foreign countries. The following notes show the result of this investigation. The notes were of particular value in connection with the compilation of a world balance sheet on cements for use of the commissioners of the United States at the Peace Conference, the data from which have been rearranged into a table showing the position of the United States in the trade of the world in hydraulic cement.

War conditions resulting in the withholding of publication of the necessary data in many countries have caused these notes to be incomplete, particularly with reference to the European countries. It is felt, however, that conditions in the cement industry were so unusual during the war that figures for belligerent countries during the war period would be of less value as an indication of peace conditions than the figures for the latest obtainable normal years. The figures available are therefore given for all countries from which information was obtained.

The metric ton is used as the unit rather than the United States barrel, the metric ton being the usual unit in the countries covered. The general statistics are taken for the most part from the official

reports of the various countries considered. Statistics of imports and exports are taken from "Foreign commerce and navigation of the United States," published by the Bureau of Foreign and Domestic Commerce, of the United States Department of Commerce.[1]

The Bureau of Foreign and Domestic Commerce issued in 1919, as Miscellaneous Series No. 79, a publication entitled "International trade in cement," which contains import statistics for countries whose imports exceeded $200,000 in value and export statistics for countries whose exports exceeded $1,000,000 in value during 1908, 1913, and also the year for which the latest figures are available. This pamphlet is sold by the Superintendent of Documents, Government Printing Office, Washington, D. C., for 10 cents a copy.

ALGERIA.

The imports of cement into Algeria amounted to 90,039 metric tons in 1913, 62,872 metric tons in 1914, and 28,362 metric tons in 1915.

ARGENTINA.

The erection of a modern Portland cement plant in Argentina is indicated by the following from Cement Era, April, 1917, page 66:

The International plans a 5,000-barrel a day plant at Sierras Bayas, which is about 200 miles from Buenos Aires, on the Trans-Andean Railroad. The plant will be erected in two units, and it is expected that the product will be used chiefly in Buenos Aires. The plant is at least a $2,000,000 enterprise.

The following note appeared in Concrete for July, 1918, page 8, cement-mill section:

Delays have occurred on construction work at Sierras Bayas, and the plant will not produce cement for six months. The town site to accommodate American employees and the crusher plant have been completed; the power plant, kilns, and coolers are 80 per cent completed, and the grinding departments are half finished; construction of the stock house is well under way. The company expects to secure an adequate coal supply from Chile.

That good progress was made during the next year is indicated by the following paragraphs from Concrete for August, 1919, page 23, cement-mill section:

According to Commerce Reports, an immense Portland cement plant is now in operation at Sierras Bayas, Argentina, the stock of which is owned entirely in the United States. The plant is located at some abandoned limekilns about 328 kilometers (203.8 miles) south of Buenos Aires. Not only does the rock contain limestone suitable for cement, but enough chips remain from the old lime works to make partly crushed material for 30 years to come. Suitable clay is also found at Sierras Bayas.

The practical difficulty in placing this cement on the market lay in the high-freight rates prevailing in Argentina, whereas cement could be shipped from New York in normal times at only $4 a ton. Satisfactory arrangements have been made, however, with the Southern Railway for a relatively low freight rate, not only in the product of the plant, but on the coal sent up from Buenos Aires as well.

The plant is most up to date in every particular, notably in its complete application of the principle of transmitting the incandescent gas as it escapes from the furnace into electric power, so that no coal is used originally in the boilers.

The present price of Portland cement in Buenos Aires is $18 to $20 gold per barrel. It is planned to fix the first price of the product of the Argentine Cement Co. at $12 gold. La Epoca, in a recent account of the new enterprise, predicts an ultimate output of 1,000,000 barrels annually; and, indeed, there is no country, perhaps in the world, where there is so great a demand for cement, there being no gravel to make roads, little timber for building purposes, and enormous public works in process of construction.

[1] The Geological Survey has not checked the following tables against the originals. The figures were converted to metric tons by the Survey.

Concrete for April, 1918, contains also the following notes:

The executive board has issued a decree, in addition to the one published March 31, 1917, which authorizes an import house of this city to introduce cement manufactured in the Republic of Uruguay, in bags or sacks; that this privilege is granted to all manufacturers of Portland cement of approved brands, provided that they are imported for the construction of national works and that their condition admits of such packing, if climatic influences will not affect their storage and location.

This step was taken in consequence of a petition made by representatives of foreign Portland cement manufacturers of well-known and approved brands, and as the council of public works has not found any technical objections which should be contrary to the privilege granted to Uruguayan cement, such privilege is to be also granted to all other brands of cement imported from foreign countries.

Cement exported from the United States to Argentina, fiscal years ending June 30, 1912–1918.

BRAZIL.

The Cement Era reported in its issue of November, 1917, page 51, that

A cement-manufacturing plant is under construction at Bello Horizonte, the capital city of the State of Minas Geraes, Brazil, to be operated by Macchiorlatti & Co. This firm claims to have invented a wood-burning oven capable of containing 2,000 calories of heat without consuming large amounts of fuel. It is reported that the plant will soon be in operation.

CUBA.

Concrete for February, 1918, page 22, cement-mill section, says:

The manufacture of cement in Cuba is no new thing, the Almendares works originally started by French capital and subsequently refinanced by Cuban interests, with American engineering talent, has been in operation for many years. But, owing to the limited production, it has not interfered materially with the imports of American cement into the island of late years. American cement has been imported to the extent of 1,000,000 barrels (170,000 metric tons) and more a year, and trade has been constantly growing.

The same journal, in the issue of May, 1918, notes that

The Cuban Portland Cement Co. has entered the earning stage. The first large sale, 2,000 barrels, has been closed. A monthly production of 50,000 barrels is expected.

Five months later the Engineering and Cement World, October 15, 1918, page 56, stated that the

demand for cement has been so great that the Cuban Portland Cement Corp. will doubtless take action to increase the crushing capacity so that 2,000 instead of the present capacity of 1,000 barrels a day can be produced. A cablegram from the general manager is as follows: "Most important to increase production. 1,000 barrels (170 metric tons) a day not sufficient. Will clean out mill stock of cement in few days. Growing demand and general outlook justified expectations steady increase to reach 2,000 barrels (340 metric tons) November or sooner. Trade reports on quality very good.

Cement exported from the United States to Cuba, fiscal years ending June 30, 1912–1918.

DENMARK.

With regard to the Danish cement industry, Concrete for October, 1917, page 31, cement mill-section, says:

According to the Commerce Reports, one of the important interests affected by the coal shortage in Denmark is the manufacture of cement. These works are now closing down and this will cause disturbance in the building trades, which are already hampered by the shortage and high price of materials and labor. * * * Denmark began the manufacture of cement in 1897 with a production of 459,000 barrels [78,070 metric tons]. In that year the net import was 459,000 barrels and the consumption 590,900 barrels. In 1913 the production was 2,965,000 barrels [504,340 metric tons] and the consumption 1,622,000 barrels. The amount of coal annually required in the Danish cement industry is about 200,000 tons.

About a year later the same journal stated [1] that

the production of Portland cement in Denmark in normal times amounted to about 2,730,000 barrels, each of 375 pounds net [about 464,370 metric tons], of which about 1,000,000 barrels [170,000 metric tons] were used in Denmark and the remainder was exported. During the war, the production has been greatly reduced on account of lack of fuel, and during 1917 a majority of the plants were closed for this reason. For the past 18 months the production has not been sufficient to meet the demands of the domestic market.

EUROPE.

Writing in Concrete,[1] L. W. Schmidt says of Europe in general:

It is expected that France, Belgium, Germany, and Austria will be capable of supplying the cement needed for rebuilding by their own factories. These countries, however, have gone through many years of war, and the cement industry in all of them has suffered very much. It is known that none of the Belgium cement works is working for private supplies, and that the German cement works have curtailed very largely the output available for building purposes. In France, nearly all of the cement made is manufactured for governmental orders. When the war is ended, it will show that none of the cement works in that part of Europe will be able at once to return to its pre-war capacity. It is very doubtful if they will be able to do so for a long time to come.

Europe has lost 9,000,000 men killed in war. It is estimated that this will reduce the industrial efficiency of Europe at the rate of 8 per cent, which will affect the cement industry.

Corresponding with an increase in the consumption of cement there is likely to be a decrease in production. This decrease may amount to as much as 15 per cent of the pre-war production in the European countries.

FRENCH INDO-CHINA.

According to R. W. Lesley[1] the employment of French capital in the establishment of works in Indo-China has been going on for some years, and the leading factory at Haifong produced during 1915 about 72,000 metric tons of cement and hydraulic lime, valued at about $1,200,000—an increase of about 35 per cent in quantity and about 50 per cent in market value over the output of 1914.

Cement imported into Indo-China, 1912 and 1914, in metric tons.

Country.	1912	1914	Country.	1912	1914
France	10,877.7	7,527.3	Singapore	0.5	.....

[1] Lesley, R. W., address before Portland Cement Association, Dec. 14, 1916.

GERMANY.

But little is known of the production of German Portland cement during the year 1916. The war conditions have largely stopped construction, but large quantities of cement have been used in the trenches. The Silesian Portland Cement Co. has advanced its prices and attempts have been made to make cartell agreements with the Rhenish-Westphalian and Central Groups of German manufacturers.[1]

The report for 1917 of the Rhenish-Westphalian Cement Syndicate states that during that year it was several times necessary to raise prices in order to keep pace with the continually increasing cost of production. The results for the year were more favorable than those for 1916, chiefly owing to the greater army demand. On the other hand, the factories were adversely affected by deterioration in the quality of the oils, fats, coals, and other materials required for their working. They suffered still more from the fact that often repairs could not be effected adequately or at the right time because of a lack of labor, while spare parts were in many cases unprocurable. The greater wear and tear to which the factories were subjected made it necessary to write off large amounts and to lay aside greater reserves for renewals. It is questionable, however, whether the deterioration of plant and material can be made good by money reserves, and in any case unwelcome consequences are bound to follow.

The interests of the industry also demand that any taxation imposed on cement production shall fall equally on competing building materials, and that protection should be afforded against the foundation of new and unnecessary concerns and against the competition of foreign products. Attention should be paid to this last point in the conclusion of commercial agreements.[2]

GUADELOUPE.

Cement imported into Guadeloupe, 1915–1917.

Country.	1915		1916		1917	
	Quantity (metric tons).	Value.	Quantity (metric tons).	Value.	Quantity (metric tons).	Value.

No exports or production.

GUATEMALA.

Cement exported from United States to Guatemala, fiscal years ending June 30, 1912–1918.

Year.	Quantity (metric tons).	Value.	Year.	Quantity (metric tons).	Value.
1912	1,681	$19,137	1916	3,207	$27,037
1913	3,149	25,244	1917	3,477	27,963
1914	2,148	19,122	1918	1,680	23,808
1915	1,813	14,127			

In addition to the cement from the United States about 3 metric tons was imported from England into Guatemala in 1916.

The following extract is from Cement Era, issue of May, 1917, page 69:

Consul Samuel C. Reat, at Guatemala City, sends details of the incorporation of a plant to manufacture Portland cement in Guatemala. The company is incorporated

[1] Mineral Industry, 1916. [2] Concrete, November, 1918, p. 55, cement-mill section.

for $250,000 and expects to employ 150 to 200 men. The company in 1914 applied to the Guatemalan Government for a concession for the exclusive privilege of manufacturing Portland cement in this country. The exclusive clause of the franchise aroused opposition and caused a protest to be filed. Later this feature was withdrawn from the application and the concession was granted in 1914 for a term of 10 years. The same year work on the company's plant, located on the road to Chinautla, 1 mile from Guatemala City, was begun and has just been completed.

To provide the necessary transportation facilities the company has built 2 miles of railroad leading from the plant to a connection with the yards and terminals of the International Railways of Central America at Las Vacas.

The company owns at the site of the plant 400 acres of land, including what is said to be a practically inexhaustible supply of limestone, together with deposits of clay and volcanic ash, which supply the elements necessary for the manufacture of cement. Except the small contracts for machinery, which were awarded in Germany prior to the European war, the company has imported all its machinery, valued at more than $50,000, from the United States. The main plant is housed in a building of wood and is known as the dry system, with rotary kilns, and has facilities for the use of oil as fuel. The plant has been constructed in sections or units, and the capacity will vary from 50,000 to 100,000 barrels of cement per annum [8,500 to 17,000 metric tons].

On account of the high steamship and railway transportation charges, cement that costs $1.80 to $2.25 a barrel in the United States is sold in Guatemala City at $7 to $7.25 a barrel. The carrying charge on cement from New York City to Puerto Barrios, formerly $0.80 a barrel, has increased since the European war to $1.50. It costs $2.60 United States gold to haul a barrel of cement from Puerto Barrios to Guatemala City, and there is an additional charge of $0.60 per barrel for unloading from steamer and loading on train at Puerto Barrios. In view of these conditions local dealers state that when the plant of the new company begins operations it will be practically impossible for American or other foreign manufacturers to meet the local competition, and that Guatamala will probably cease importing cement altogether.

HAITI.

Cement exported from the United States to Haiti, fiscal years ending June 30, 1912–1918.

Year.	Quantity (metric tons).	Value.	Year.	Quantity (metric tons).	Value.
1912	3,997	$30,248	1916	5,728	$46,565
1913	5,668	43,336	1917	7,004	63,185

1915	4,911	57,859			

HONGKONG.

Concrete for June, 1918, page 110, cement-mill section, says:

The chief Hongkong cement interest—the Green Island Cement Co.—which has long been one of the principal cement interests in the Far East, has earned during the past year (1917) a gross profit of $495,255 Hongkong currency, as compared with

$610,150 the previous year. The difference is ascribed to the high price of fuel, the shipping difficulties, the high exchange value of silver, and the difficulties of securing raw materials. As to fuel the manager of the cement company referred to stated at the annual meeting that it is now paying $32 local currency, or $24 gold, for coal for which it paid $20 local currency, or $6 gold, at exchange current a year ago, and $10 local currency, or $6 gold, at exchange current the year before.

The company has found it necessary, owing to disturbed conditions in China and owing to the alleged hostile action on the part of Chinese interests, to go all the way to Tonkin for most of its limestone, although stone has come forward from China in larger supplies the past year.

Trade with the Philippines during the past year remained at about the same volume as the previous year, the shipments to the islands being 3,150 short tons; but the value increased from $61,838 for 1916 to $106,261 for 1917. The business is far below its normal volume, however, the value of the exports in previous years being $78,412 in 1915, $111,476 in 1914, $160,289 in 1913, $239,194 in 1912, $349,616 in 1911, and $265,638 in 1910. Since 1911, when it reached its highest point, cement from Japan, Indo-China, North China, and from local sources has been supplying the Philippine market.

No regular trade from United States to Hongkong—1914, 335 barrels, at $425; 1916, 41 barrels, at $103.

1915	2	19			

Concrete for October, 1918, page 44, cement-mill section, quotes as follows:[1]

New Zealand has passed through a nine months' period of selling cement below cost. A new and large company started its operations shortly after 1912 and put cement on the market during the early months of 1917, but owing to the war conditions trade fell off very considerably, the result being a cutting of prices.

The outcome has been an amalgamation of the three companies in the immediate neighborhood of Auckland—viz, the Dominion Portland Cement Co. (Ltd.), the New Zealand Portland Cement Co. (Ltd.), and the Wilsons Portland Cement Co. (Ltd.), under the name of Wilsons (N. Z.) Portland Cement (Ltd.), with a paid-up capital of $3,000,000. George Elliott and F. W. Wilson (formerly of Wilsons Cement Co.) have been appointed chairman of directors and secretary, respectively. Mr. Reed, of the New Zealand Co., has been appointed sales manager, and T. H. Wilson, of the Wilsons Co., has been appointed works manager and engineer of the three plants, with F. Rhodes, of the New Zealand Co., as assistant.

The subjoined abstract describing the plant of the Dominion Portland Cement Co. (Ltd.) is taken from Concrete for May, 1918, page 43, cement-mill section:

The plant of the Dominion Portland Cement Co. (Ltd.) is located at Tikorangei, on Whangarei Harbor, Auckland, New Zealand, about 60 miles due north of the city of Auckland.

The materials used are high-grade limestone and argillaceous cement rock, which are obtained directly back of and about three-quarters of a mile from the plant.

Quarry: Steam shovel loading to 7-ton quarry cars.
Crushing: No. 6½ gyratory crushers, limestone to rolls, cement rock to hammer mills.
Rock driers: 2 by 7 by 70 foot rotary brick-lined driers.
Storage: 40 hours run.
Raw mill: 6 by 42 inch Fuller mills, fan discharge—75 horsepower vertical motors.
Storage: 30 hours run (kiln storage).
Kilns: 2 by 8½ by 160 foot four-tire rotary kilns.
Coolers: 2 by 7 by 70 foot rotary coolers.
Clinker storage: 40,000 to 45,000 barrels.
Finish mill: 4 by 57 inch Fuller dreadnaught mills.

[1] Letter from an official of Wilsons Portland Cement (Ltd.), Portland, Whangarei County, New Zealand.

Stock house: 15 bins, 2,000 barrels capacity each.
Coal supply: By water or rail.
Coal crushers: 24 by 18 inch crushing rolls to 1 inch or less.
Coal driers: 5½ by 42 foot indirect fired rotary drier.
Coal pulverizers: 2 by 42 inch Fuller mills.
Electric power: From hydroelectric installation owned by company transmitted at 33,000 volts, transformed to 400 volts, 3 phase, 50 cycles.
Plant capacity: 1,600 barrels per day.

The Cement Era of February, 1917, page 74, says:

The Dominion Portland Cement Co. mill is larger than all other cement plants in New Zealand combined. The company is formed entirely of New Zealand capital and it is intended to send a good deal of the product to Australia, 1,200 miles away, which is not a big freight distance for that part of the world.

RUSSIA.

Concrete for June, 1917, page 113, cement-mill section, gives the following abstract of an article in the journal of the Russian-American Chamber of Commerce, Moscow, January, 1917:

Previous to the war, development had already been noticed in the cement industry. According to data published at the congress of cement producers in 1915, the production for four recent years was as follows: 1912—10,000,000 barrels of 10 poods (361.13

[1] Graham, W. B., War Trade Board Bur, Research.

pounds) each [or about 1,638,000 metric tons]; 1913—12,920,000 barrels; 1914—20,000,000 barrels (estimated); 1915—28,000,000 barrels (estimated). The number of cement works was 33 in 1912 and was expected to reach 66 in 1915. However, a number of the new works included in the latter estimate were still under construction, and part of their equipment ordered in Germany had not been delivered. The average output of each concern, which in 1912 was about 300,000 barrels, reached about 425,000 barrels in 1915. Few works are now constructed in Russia with an annual output of less than 500,000 barrels.

On January 1, 1911, the capital of the six cement companies whose shares were quoted on the Petrograd exchange aggregated $4,341,000; on January 1, 1914, the 11 cement-producing concerns quoted on the same exchange represented a capital of $19,956,000. The average capital was thus $721,000 in 1911 and $1,803,000 in 1914. The dividend paid by one company increased from 4.5 per cent in 1910 to 25 per cent in 1912; by a second company from 8 per cent in 1910 to 14 per cent in 1912; and by a third company from 12 per cent in 1910 to 24 per cent in 1912.

Although the cement industry was developing rapidly in the last years before the war, it will be necessary to increase the production five to ten times in order to avoid a cement famine after the war. There are unfortunately no firms in Russia to undertake the construction of cement works. Previous to the war such construction was carried out by German firms and one Danish firm, but the American industry producing the equipment for cement works could very well compete with these firms. The cement industry in Russia is also regarded as a promising field for the investment of American capital.

ST. PIERRE.

Cement imported into St. Pierre, 1912 and 1914, in metric tons.

Country.	1912	1914
France	35.0	28.8
United States	27.6	1.2
Canada	3.2	22.0
	65.8	52.0

The reexports of cement from St. Pierre in 1912 and 1914 were to Newfoundland and amounted to 5.2 metric tons in 1912 and to 4.7 tons in 1914.

SALVADOR.

Cement imported into Salvador, 1914–1916.

Country.	1914		1915		1916

SOUTH AFRICA.

In Africa there are two large cement works—the Pretoria Portland Cement Co., which was established some years ago, and the Whites South African Cement Co., a subsidiary company of the Associated Portland Cement Manufacturers of England. With the decreased shipping facilities for cement from Europe to Africa, both of these plants have been very busy. [1]

Cement imported into South Africa, 1911–1917, metric tons.[a]

Country.	1911	1912	1913	1914	1915	1916	1917

a Preference of 6 cents per barrel (400 pounds) as rebate on British goods originating in Great Britain or colonies.

SPAIN.

Owing to the falling off of imports the production of cement in Spain has largely increased, and that country now has nine plants devoted to the making of Portland cement, five of which are of comparatively recent construction. They produce now 350,000 tons of cement and are being increased to a capacity of 500,000 tons. This will take up any demand for cement from the outside. An interesting fact is that there are 61 plants in Spain making a natural cement, of which 255,000 tons were produced in 1914.[1]

SUDAN.

Cement imported into Sudan, 1907–1915, in metric tons.

1907	20,917	1912	3,521
1908	18,525	1913	5,071

1910	4,581	1915	1,272
1911	4,775		

SWEDEN.[2]

The manufacture of cement in the form known as Portland cement is not of very old date in Sweden, though the sort of hydraulic mortar made of burnt alum shale powder and lime was formerly used in connection with earlier canal structures. Cement was employed as early as 1860, but then only to the extent of 1,180 tons. The first cement factory in Sweden was established at Lomma, in Skane, in 1871, on the initiative of Prof. Otto Torell and Otto Fahnehjelm, an engineer. Clay of suitable quality is to be found there in unlimited quantities, and lime was obtained from the neighboring place of Limhamn and sent by sea to Lomma. This was the beginning of the Scanian Cement Co., the first manager of which, R. F. Berg, has done a great deal toward furthering the development of the cement industry in Sweden. In Sweden the natural conditions necessary for the manufacture of cement are amply satisfied, owing to the great resources of suitable raw material, and, after the Lomma factory (which was closed in 1904) other factories were started at Limhamn (established by the Scanian Cement Co.); Visby, 1885; Öland, 1888; Hällekis, 1892; and, at Klagshamn and Maltesholm, 1898. The latest factory is the Ifö Cement Factory

[1] Lesley, R. W., address before the Portland Cement Association, Dec. 14, 1916.
[2] Sweden, Historical and Statistical Handbook, 1914.

(1909). The sale of the products of all these factories is negotiated through the Swedish Cement Selling Co., of Malmö. Owing to its excellence, this Swedish cement has obtained a first-class reputation, also for export, at first under the name of Lomma cement.

The output of the factory at Lomma was at first 20,000 casks of cement yearly. The capacity of production of the Limhamn factory is now about 900,000 casks yearly. When working at full pressure, all the Swedish factories can now produce about 2,500,000 casks yearly. The product was 339,618 tons (1,187,000 casks) in 1912, with a value of 9,621,000 kronor. Fourteen hundred and forty-seven workmen were then employed in the manufacture of cement. With the year 1889, when cement became subject to a duty of 40 öre per 100 kegs, the manufacture rose somewhat, and later increased rapidly when the duty was in 1895 increased to 60 öre per 100 kegs. The manufacture and export have steadily increased since.

Of the total exports in 1912, amounting to 127,141 tons, 42,420 tons went to Russia, 33,286 tons went to Argentina, 22,155 tons to the Sunda Islands, 14,810 tons to Finland, and 12,189 tons to Denmark; the remainder was distributed over British South Africa and Brazil.

Statistics of cement industry in Sweden.

Year.	Production.	Imports.	Exports.	Consumption.
1875	$59,228	$71,020	$31,892	$98,356
1876–1880	106,664	76,380	54,672	128,372

UNITED KINGDOM.

Concrete for February, 1918, page 21, cement-mill section, quotes from a letter from H. E. Brooks, managing director of the Associated Portland Cement Manufacturers (1900) (Ltd.), London, England, as follows:

Since my previous letter was penned a very considerable change has taken place, and this is due in the main to two causes:

1. The scarcity of timber, consequent on the difficulty of obtaining supplies from the Scandinavian countries, causing the substitution of Portland cement concrete for timber and steel in all kinds of building operations for war purposes, both within the United Kingdom and in the war zone.

2. Stocks, which were accumulating in the early months of the last year, have for some time been falling. Only very moderate quantities are now in maker's hands,

and there is every prospect of further reduction, notwithstanding the presence of winter.

At the present time the scarcity of labor due to the war is being acutely felt and constitutes the most serious of our difficulties in the production of cement; but as almost all the cement now used here is for purposes directly or indirectly necessary for the prosecution of the war, the various government authorities concerned are giving us what help they can to improve the position. Those * * * who have taken note of the varying conditions of the cement trade in other lands * * * may be interested to learn that, although the production here is still only about one-half the pre-war tonnage, conditions have improved, and the increased demand seems likely to continue.

Domestic cement exported from the United Kingdom, 1907–1917, in metric tons.

a Fiscal year. b Half a year lacking on account of change to fiscal year.

URUGUAY.

Concrete for August, 1918, page 106, cement-mill section, says:

At present practically all cement used in Uruguay is produced by the Fábrica uruguaya de Portland, of Messrs. Metzen-Vincenti y Cía., located at Sayago (Montevideo). This mill began operations shortly before the outbreak of the European war, after thorough experiments with native materials running back as far as 1909 had been made by German experts. It has a concession from the Uruguayan Government giving it certain privileges as respects taxation, which concession expires in 1928. The company has its own limestone quarries situated in the Department of Minas. Stone is extracted by modern methods including the use of compressed air drills. The original equipment for the making of cement was furnished and installed by the Amme, Gieseche und Konegen Aktien-Gesellschaft, Braunschweig, Germany. The plant has subsequently been expanded and now has a capacity of over 400,000 barrels (about 68,400 metric tons) per year. The plant and its dependencies represent an investment of $827,000. The product, which is known as the "Metzen" brand, is said to be a gray cement of very good quality, comparing favorably with imported cement. It is already well known in Argentina. It is put up for sale in 50-kilo (110 pounds) sacks, and barrels, weighing 180 kilos (397 pounds) gross and 170 kilos (375 pounds) net.

Metzen cement was quoted on April 1, 1918, at 2.85 pesos ($2.95) per sack of 50 kilos and 9.80 pesos ($10.13) per barrel of 180 kilos gross. Prices are for cement delivered at Montevideo or at railway station or dock (Montevideo). The company buys back sacks at 8.3 cents each.

The import duty is equivalent to a specific rate of 25.5 cents (United States) per 100 pounds gross. There are, further, certain minor charges, which, according to an importer, bring the actual entrance charges on imported cement up to roughly 1.05 pesos ($1.09) per barrel. The import duty and charges stated are applicable to cement imported from all countries.

The remarkable falling off of imports of cement, as compared with the pre-war period, is due to the lack of activity in building and construction work, the difficulty of securing cement from abroad, and the rapid development of the home industry. As a result of the latter, Uruguay is now exporting cement.

The following extract is from the Engineering and Cement World, of October 5, 1918:

The Government of Uruguay has appealed to the Philadelphia Chamber of Commerce to interest American cement manufacturers in the erection of a modern cement plant in or near Montevideo. Uruguay has been dependent for its manufactured cement on a plant owned and operated by Germans, who have charged exorbitant prices for their product and have been independent and arbitrary in their dealings with the Uruguayan Government.

The communication sent to the Philadelphia Chamber of Commerce states that the Uruguayan Government desires to boycott this German plant and to induce American cement manufacturers to consider favorably the erection of a plant at Montevideo, and that the Government is willing to allow a number of concessions.

Cement exported from the United States to Uruguay, fiscal years ending June 30, 1912–1918.

POSITION OF THE UNITED STATES IN THE HYDRAULIC CEMENT TRADE OF THE WORLD.

The following table, prepared by Robert S. Schultz, jr., shows the maximum recent production of cement in all the producing countries of the world, as far as ascertainable, as well as the average normal consumption of cement throughout the world in the years preceding the war or during the war, and indicates the future prospects of the industry. The table shows at a glance the leading position of the United States in the hydraulic cement trade of the world.

Statistics of the hydraulic cement trade of the world,[a] showing position of the United States.

[Prepared by Robert S. Schultz, jr. Statistics approximate and subject to revision. Quantities in metric tons.]

Country.	Maximum recent production.			Average normal consumption.		Probable maximum exportable surplus.	Probable minimum necessary imports.	Expected effect of known reserves on future output.	Comments.
	Quantity.	Year.	Approximate percentage of world's total.	Quantity.	Year.				
United States	**15,938,800**	1917	**43.23**	13,472,200	1911–1914	**2,466,600**	.....	Possible 5–10 per cent increase in production.	Enormous reserves of raw materials. Production limited by plant capacities. Practically entire export trade is with South America.
North America, exclusive of United States:									
Canada	1,412,300	1913	3.83	1,391,900	1912–1913	20,400	.....	Probable large increase	Industry growing very rapidly before the war. Several new plants completed. No necessity of imports and probable small surplus for export.
Mexico	(b)	.....	.....	61,000	1910–1913	.....	61,000	Possible increase	Several very small mills.
Cuba	103,600	1918	0.28	127,000	1915–1916	.....	23,400	New plant operating	New plant—capacity 600,000 barrels or 103,900 metric tons—completed April, 1918. Controlled by United States capital.
British West Indies and British Guiana.	.....	.....	.....	20,800	1911–1914	.....	20,800	.....	No production known—demand well supplied by imports.
Central America	10,200	.....	0.03	16,300	.....	.....	6,100	Small production	Small mill in Guatemala—will about supply domestic demands. Controlled by United States capital.
South America:									
Argentina	.....	1918	.....	447,000	1911–1914	.....	447,000	Production of 172,720	One plant building—1,000,000 barrels yearly capacity. Raw material available for other plants. Several very small ones operating.
Bolivia, Ecuador	.....	.....	.....	7,500	1910–1914	.....	7,500	.....	
Brazil	.....	.....	.....	562,900	1913	.....	562,900	.....	
Chile	20,300	1914	0.06	167,700	1913	.....	147,400	.....	Two plants operating. Large reserves of raw materials, making possible large production with increased demand.
Colombia	.....	.....	.....	12,200	1917	.....	12,200	.....	
Peru	.....	.....	.....	30,000	1911–1914	.....	30,000	.....	
Uruguay	71,100	1917	0.19	58,700	1911–1913	12,400	.....	No change	One small plant operating. Production sufficient for domestic demand with slight surplus available for export.

Venezuela, Paraguay				10,700	1916–1917		10,700	One small mill in Venezuela—production insufficient for domestic demand. Paraguay ordinarily uses little or no cement, but in 1916–1917 considerable cement was imported for construction of packing plant.
Europe:								
Austria-Hungary	609,600	(c)	1.65	530,300	1911–1913	79,300		Large pre-war producer. Condition of industry unknown.
Belgium	2,032,000	(c)	5.51	1,207,000		825,000	Great temporary decrease.	Large producer of both natural and Portland grades before the war. Many mills probably destroyed. Some mills known to have been operated by Germans. Will probably require very large imports for reconstruction.
British Isles	3,048,000	1913	8.26	2,361,200	1912–1913	686,800	No probable change	Industry about stabilized between production and demand prior to war. Exports chiefly to India and eastern South America.
Bulgaria				15,400	1907–1911		15,400	
Denmark	503,900	1913	1.36	278,400	1911–1914	225,500	Probable increase	Industry overdeveloped prior to war. Production and exports restricted by agreement with Germany.
France	1,930,400	1913	5.24	1,494,500	1910–1912	435,900	Temporary decrease	Large production of both natural and Portland grades. Mills mostly small. Many mills in devastated area probably destroyed.
Germany	7,193,300	1912	19.51	6,070,600	1910–1913	1,122,700	Probable large increase	Very large producer before the war. Industry overdeveloped and production restricted by agreement. Exports restricted by agreement with Belgium, England, and Denmark.
Greece				1,000	(c)		1,000	
Holland	2,100	1914	0.01	310,900	1910–1913		308,800	One very small mill.
Italy	847,300	1910	2.30	823,000		24,300	Probable increase	Large production, mainly of natural grade. Number of mills being modernized before the war.
Norway	(b)			23,900	1911–1914		23,900	Probable production	At least one company organizing. Probable sufficient production for domestic demand.
Portugal				36,000	1913		36,000	
Rumania and Serbia	16,300	1911	0.04	19,600	1910–1913		3,300	Sixty-six plants either active or under construction in 1915. Effect of war unknown.
Russia, Finland	457,200	1915	1.24	635,000	1912–1914		177,800	Probable increase	Probable large demand with return of civil stability.
Spain	525,300	1912	1.42	601,500	1912–1914		76,200	Possible increase	Producer of both natural and Portland grades before war. Mills being modernized. Production will probably supply domestic demand.
Sweden	391,200	1913	1.06	249,900	1912–1914	141,300		No probable change	Domestic consumption will probably increase slightly. Exports principally to Russia and to Argentina.
Switzerland	254,000	(c)	.69	237,300	1911–1914	16,700			Large producer.
Turkey	50,800	1914	.14	57,400	1911		6,600		Two small plants. Production insufficient for domestic demand.

[a] Estimated.

CONCRETE SHIPS IN 1918.

By Robert W. Lesley.[1]

During 1917 and 1918 every effort was made and every nerve strained to put American troops on the battle front with the least possible delay. American energy was largely concentrated upon the increasing of American shipping in order to provide passage for the millions of soldiers and the millions of tons of material which it was felt were the necessary supply for our part in the war. The Emergency Fleet Corporation, with practically unlimited appropriations, engaged vigorously in the construction of yards for the building of wooden ships and also erected at a number of points along the Atlantic coast enormous yards for the construction of fabricated steel vessels. Even this large program seemed insufficient to meet the emergency, and it was under these conditions that the Concrete Ship Section of the Emergency Fleet Corporation came into existence and began the construction of what were known as "stone ships", as described in the first article on concrete ships published by the Geological Survey in its chapter on cement in Mineral Resources for 1917.

The staff of concrete engineers and naval architects formed to make an exhaustive investigation of the subject and develop designs for concrete ships gathered much valuable information, and early in 1918 contracts were let to the Fougner Concrete Shipbuilding Co., of New York, and the Liberty Shipbuilding Co., of Boston, for the construction by each company of a 3,500-ton concrete vessel according to their own designs, the building of subsequent ships under the contracts being contingent upon the success of the first ship. After a proposition had been brought before Congress to appropriate $50,000,000 for concrete ships, it was found that the Emergency Fleet Corporation itself had funds available to do this work, and, in accordance with the plans adopted in the fabricated shipyards built under Government auspices, five yards were established for the construction of concrete ships by agency contract under the direct supervision of the Concrete Ship Section of the Emergency Fleet Corporation. The locations of the yards and the agency contractors were as follows:

Jacksonville, Fla.—A. Bentley & Sons Co.
Mobile, Ala.—Fred T. Ley Co.
Wilmington, N. C.—Liberty Shipbuilding Co.
San Diego, Calif.—Scofield Engineering Co.
Oakland, Calif.—San Francisco Shipbuilding Co.

The original program of construction at these yards provided that each company should have the building of eight 7,500-ton vessels and that these and the two already mentioned above should constitute a building program of 42 vessels with a total capacity of 307,000 tons.

With the adoption of a concrete-ship program by the Emergency Fleet Corporation, general interest was awakened not only in other departments of the Government but also among shipowners generally, and a lively discussion arose between the Shipping Board and the Army Transport Service over the desire of the latter branch to build concrete ships. In the ordinary commercial field, the construction by private yards of concrete vessels was for a time hindered by the attitude of the Shipping Board, which declined to give permission for general construction of vessels of this type by other private yards.

[1] Associate American Society Civil Engineers.

Contracts for concrete vessels were let by the Navy Department for twelve 500-ton coal barges, by the Inland Waterways Commission for twenty-one 500-ton concrete barges to be used on the New York State barge canal, and by the Army Transport Service for water tank boats, river steamers, and car-ferry floats. The result of all this was that just as the war was approaching its end, namely, in September, 1918, concrete-ship construction was in full swing. The following table indicates the total tonnage either completed or under construction or contract in the year 1918:

Concrete ships and barges in the United States and Canada, in 1918.

	Dead weight tonnage.
Completed:	
S. S. *Faith*	5,000
S. S. *Concretia*, Montreal	350
Ocean Barge & Transport Co., Seattle, scow	550
J. W. Thompson Co., New Orleans, 2 barges	1,100
Louis L. Brown Co., New York, 1 barge	700
Louis L. Brown Co., 1 barge for Navy Department	500
Fougner Concrete Shipbuilding Co., New York, 1 oil barge for Standard Oil Co	370
American Chain Co., Bridgeport, Conn., 1 barge	100
Harrison Barge, Long Beach, N. Y. (800 tons, estimated)	800
Marl Barge, Union City, Mich	300
	9,770
Government work under contract:	
Concrete Ship Department:	
Fifty 3,500-ton cargo ships, Liberty Shipbuilding Co., Brunswick, Ga.	175,000
Five 3,500-ton cargo ships, Fougner Concrete Shipbuilding Co., Flushing, L. I.	17,500
Forty-two vessels, forty 7,500-ton oil tankers, with two 3,500-ton cargo ships to be built at five Government and two private yards	307,000
Navy Department:	
Eleven 500-ton coal barges (one completed by L. L. Brown Co.)	5,500
Twenty-one 500-ton barges	10,500
War Department—Army Transport Service:	
Twelve 265-foot car-ferry floats, 1,100 tons	13,200
Five 100-foot water-tank boats (285 tons, estimated)	1,425
Fourteen 130-foot river steamers (390 tons, estimated)	5,450
	535,575
Private contracts:	
One 2,000-ton cargo ship, Houston, Tex	2,000
One cylindrical oil tanker, New Orleans, La. (estimated)	1,500
One oil tanker, Newburgh, N. Y	2,800
One seagoing barge, Vancouver	1,500
Two 225-foot cargo ships, Cleveland, Ohio (estimated)	6,000
Two 150-foot tow barges, Cleveland, Ohio (estimated)	1,200
One barge, 400 tons, Concrete Boat Co., San Francisco, Calif	400
One 600-ton barge, Chas. O. Heyworth, Chicago, Ill	600
One tugboat, 25 tons; 10 barges, 130 tons, International Constructors, Chicago, Ill	1,325
Three oil barges, 400 tons (estimated), Fougner Concrete Shipbuilding Co	1,200
	18,525
Summary:	
Completed	9,770
Government work under contract	535,575
Private contracts	18,525
	563,870

With the cancellation of many contracts for wooden ships, for fabricated steel ships, and for vessels of other classes by the Emergency Fleet Corporation, the concrete-ship program underwent reductions. At the end of 1918 the total of Government concrete vessels under contract was largely reduced, as is shown by the table below:

Government concrete boats under contract at end of 1918.

Government agency.	Type of boat.	No.	Name of contractor.	Location of yard.
Emergency Fleet Corporation.	3,500-ton freighter	1	Fougner Concrete Shipbuilding Co.	Astoria, L. I.
Do	3,000-ton freighter	1	Liberty Shipbuilding Co.	Brunswick, Ga.
Do	3,500-ton freighters	2	do	Wilmington, N. C.
Do	7,500-ton tankers	2		
Do	7,500-ton freighter	1	San Francisco Shipbuilding Co.	Oakland, Calif.
Do	7,500-ton tankers	2	F. T. Ley & Co	Mobile, Ala.
Do	7,500-ton freighter	1		
Do	7,500-ton tankers	2	A. Bentley Sons	Jacksonville, Fla.
Do	do	2	Scofield Eng. Co	San Diego, Calif.
Navy Department	500-ton harbor lighters	4	Ambursen Construction Co.	Little Ferry, N. J.
Do	do	4	L. L. Brown Co	Peekskill, N. Y.
Do	do	4	S. G. Beskin	Beacon, N. Y.
Railroad Administration. (Construction supervised by Emergency Fleet Corporation.)	500-ton New York Barge Canal barges.	8	Holler-Davis & Flood Co.	Fort Edward, N. Y.
Do	do	4	Caldwell-Marshall Co	Tonawanda, N. Y.
Do	do	5	Grayhaven Shipbuilding Co.	Detroit, Mich.
Do	do	4	Cummings Structural Concrete Co.	Ithaca, N. Y.
War Transport Branch War Dept.	130-foot river boats	9	(Contracts not completed.)	
Do	100-foot water tankers	5	Great Northern Shipbuilding Co.	Vancouver, Wash.
Do	265-foot car floats	6	Liberty Shipbuilding & Transportation Co.	Cleveland, Ohio.
Do	do	6	L. B. Harrison Co	Athens, N. Y.

The total number of vessels of the 7,500-ton class to be built in the agency yards by the Emergency Fleet Corporation was reduced to 14, distributed as shown in the table, and the work of the other departments of the Government was also reduced from the original plans. In private yards a few barges were under construction at the end of the year, but no private ships were being built.

The concrete shipbuilding program may be said to have been justified by the *Faith*, inasmuch as this cargo steamship, built in San Francisco and launched March 14, 1918, after making the trip described in this report in Mineral Resources for 1917, spent most of the year 1918 on deep-sea voyages. She left Vancouver with a cargo of lumber for Chile, then proceeded north with a cargo of nitrate by way of the Panama Canal to New Orleans, thence with a mixed cargo to Habana, which she left on November 7, 1918, and arrived in New York on November 14 with 20,000 bags of sugar, having made all these journeys without damage or injury and having demonstrated the value of concrete as a shipbuilding material.[1]

It may be said that the year 1918 was deficient in the actual production of concrete ships and that the curtailing of the Emergency Fleet program for vessels of this type may prove a handicap in the future development. On the other hand and in strong contrast to

[1] A photograph of this ship at dock in New York appeared in Leslie's Magazine, Jan. 4, 1919, p. 20.

this contention, the year 1918 was productive, first, of a practical demonstration in a large way of an actual seagoing steamship of large carrying capacity which made long ocean voyages, and proved her stability and seaworthiness. Coupled with this actual physical demonstration of the value of the concrete ship as a practical means of ocean transportation, there was gathered in the year 1918 a large mass of most valuable scientific and technical knowledge of the construction of concrete ships. The first ship, the *Faith*, may be said to have been built upon faith without great research or prolonged study; her lines were clumsy and her speed was slow. The later vessels constructed or under construction are of more delicate lines, some of them almost yacht-line in form, and represent the aggregate results of deep study by the naval and concrete engineers gathered in the Concrete Ship Section of the Emergency Fleet Corporation. Their problems were not easy.

It was at first thought that ordinary labor could put together concrete ships much more easily than skilled labor could handle ordinary steel ships of fabricated vessels. It was found, however, that the placing of the steel members of the concrete ship was difficult and expensive. The bending alone required great accuracy and large delays in construction. The steel construction had to be finished as a whole, so that the forms might be placed and the concrete poured at one time, thus avoiding spots or cleavage points. Both placing of the plates and the stripping of them from the completed concrete were also full of difficulty, and it was not until a special method of hammering the concrete into place by pounding on the interior forms was developed that it was found possible to get the mix into all the nooks and crannies formed by the interlacing steel wires and rods. The stability and seagoing qualities of the concrete ship having been demonstrated, the engineers were forced as the war emergency began to disappear and commercial requirements became manifest to develop economies in construction and in every way to lighten the concrete ship without destroying its strength. To this end many improvements have been made in the design of the ship and in the handling of the steel members and of the concrete itself. There were no precedents for the concrete ship; no strain studies; no historical figures to refer to either in type of design or in type of construction. Methods, however, are now being developed for improving the bending and placing of the steel, and, more important than all other developments, great progress has been made in lightening the aggregate. This latter improvement has for its purpose the placing of the concrete ship on an economical parity with the steel ship of commerce. A light and strong aggregate has been developed by highly calcining clay in an ordinary rotary cement kiln. This aggregate, crushed to quarter inch and half inch size, makes a 1:2 concrete weighing about 100 pounds per cubic foot and breaking in compression at 4,000 pounds at 28 days. With this aggregate, which is practically light enough to float in water, it is expected that the standard 150 pounds per cubic foot concrete which had hitherto been used will be reduced to 100 pounds and that the present ratio of dead-weight to full-load displacement, which with the heavier concrete stood at 52 for the concrete vessel as compared with 68.6 for the steel ship, will be increased to 62 for the concrete vessel.

137536°—M R 1918—PT 2——40

With these figures in mind, the future of the concrete ship seems to depend largely on cost. According to figures given by engineers who have been in close touch with construction work, the cost of steel ships ranges from $210 to $250 per ton complete, whereas that of concrete ships ranges from $150 to $200 per ton. Thus, to take a general average, the original cost of a concrete vessel of 7,500 tons would be $300,000 cheaper than a steel ship of like capacity. In view, however, of the difference in ratio of dead weight to displacement, the concrete ship would be at a material disadvantage as above shown, and it thus becomes a question as between the repairs, operating expenses, and interest charges on the concrete ship as compared with the steel ship of similar size. The concrete ships so far constructed under the Emergency Fleet Corporation will certainly show costs far in excess of those above estimated because of the fact that each of the yards at which these vessels were to be constructed was planned with four ways upon which eight ships were to be built. If, therefore, all the overhead of this extra construction, including blacksmith shops, offices, bending shops, cement warehouses, and administration expenses, is to be charged against the largely reduced number of vessels built in each yard, as compared with the vessels originally planned and contracted for, the concrete ship will appear at a serious disadvantage. It would seem to be a fair statement that the cost of the Government-built concrete ships will not be excessive if each ship is charged only with its percentage of the overhead and other expenses as originally contemplated rather than be charged with the whole burden caused by the reduced output due to cancellation of contracts.

The first of the Government ships was launched on December 4, 1918, at Brunswick, Ga. She was named the *Atlantus* by Mrs. Woodrow Wilson and was christened by Mrs. Matthew Hale, wife of the plant manager. She was built by the Liberty Shipbuilding Co., agent of the Emergency Fleet Coporation. She has 3,000-ton capacity, with 1,400 horsepower, measures 260 feet in length, with a breadth of 43 feet 6 inches, and has a draft of 22 feet 6 inches. She has a 5-inch wall of reinforced concrete, which, compared with the ordinary wooden ship of the same size, averages 19 inches less and is much lighter, the concrete used being of special aggregate developed by the Concrete Ship Section of the Emergency Fleet Corporation and weighing about 118 pounds, as against approximately 150 pounds per cubic foot of the ordinary concrete. The vessel is at sea under the direction of the Emergency Fleet Corporation.

In summing up the status of the concrete ship Mr. R. J. Wig, head of the Concrete Ship Section of the Emergency Fleet Corporation, gave the following statement:

1. All analytical investigations so far made demonstrate that the concrete ship can be designed so as to carry all the strains which come upon a ship just as safely as a steel ship.

2. The tare weight of a concrete hull has been reduced to such an extent by the development of a light-weight aggregate that it has a proportionate carrying efficiency greater than wooden ships and only slightly less than steel ships.

3. All available experience with concrete ships to the present time does not demonstrate any structural weakness which might indicate unsoundness in the theory of design of concrete ships or probable limited life.

4. While concrete ships of small size are being built in many places throughout the world, the large ship (over 3,000 tons) is being developed in the United States.
5. There is no perceptible difference in the frictional resistance offered by a concrete ship as compared with a steel ship.
6. Our general knowledge of reinforced concrete as compared with steel structures makes the success of its further adoption for ship construction appear a certainty, but actual experience is lacking, and therefore its future can not be predicted with absolute certainty.

Concrete ship construction abroad.—The crying need for ships caused by the submarine warfare was as acute in England as in the United States, and a department of the admiralty was established to construct concrete ships. Some 20 yards were established and contracts for more than 200 boats of all kinds were awarded. The principal one of these is the *Armistice*, of 1,100 tons, built in 1918 at Barrow-in-Furness. It has already made seven voyages with success. According to reports, it has not cost $100 for repairs since leaving the builders' yards. Numerous firms in England, Scotland, and Ireland are building steam tugs and barges of concrete for the admiralty and inland water transport department in England.

France has also been active in concrete ship construction, and Italy has completed a number of barges. Reports of active construction of concrete vessels come from Sweden, where contracts have been made for a number of ships, and also from Spain, where at Malgrat yards plans have been made to build simultaneously 30 concrete vessels, some of them up to 6,000 tons capacity. The first Spanish concrete ship is already at sea.

Even in the Far East construction of this type has gone on—in Cochin-China, at shipyards on Wang Poo River, China, and in Singapore, India. Japan has been testing silico-concrete as a material for shipbuilding, and claims are made that a boat of this material will be 25 per cent lighter than she would have been under ordinary concrete construction and also 25 per cent lighter than if steel had been used.

MICA.

By Waldemar T. Schaller.

PRODUCTION.

The mica produced and sold in the United States in 1918, as reported to the United States Geological Survey, amounted to 3,114 short tons, valued at $764,940. The sheet mica marketed in 1918 amounted to 1,644,200 pounds, an increase in quantity of 29 per cent over that of 1917 but a decrease of $22,064, or nearly 3 per cent, from the value, $753,874, in 1917.

The compiled statistics of sheet mica have always lumped together the cut and the uncut; the clear, slightly spotted, and stained, and the heavily spotted and stained; the punch and the washer mica; so that no information is available as to the quantity of clear sheet mica produced with regard to either size or quality. Moreover, not all clear mica is suitable for all high-potential electrical work, and no record is available of the quantity of domestic sheet mica produced that would comply with certain rigid specifications.

The statement that the United States produced so many pounds of sheet mica therefore gives no information as to how much of this was clear, or how much was above a certain size, or how much was suitable for specific purposes. For this reason in making a comparison between domestic production and imports it must be remembered that, whereas the imported mica consists largely of clear sheets of good quality, the domestic product includes all qualities from clear to heavily spotted and stained.

The quantity and value of the scrap mica produced—2,292 short tons, valued at $33,130—were the smallest reported since 1906.

Mica produced and sold in the United States, 1909–1918.

Year.	Sheet mica.		Scrap mica.		Total quantity (short tons).	Total value.
	Quantity (pounds).	Value.	Quantity (short tons).	Value.		
1909	1,809,582	$234,482	4,090	$46,047	4,995	$280,529
1910	2,476,190	283,832	4,065	53,265	5,303	337,097
1911	1,887,201	310,254	3,512	45,550	4,456	355,804
1912	845,483	282,823	3,226	49,073	3,649	331,896
1913	1,700,677	353,517	5,322	82,543	6,172	436,060
1914	556,933	278,540	3,730	51,416	4,008	329,956
1915	553,821	378,259	3,959	50,510	4,236	428,769
1916	865,863	524,485	4,433	69,906	4,866	594,391
1917	1,276,533	753,874	3,429	52,908	4,067	806,782
1918	1,644,200	731,810	2,292	33,130	3,114	764,940

This table has been compiled from the figures reported by the producers. The total therefore includes cut mica ready for the trade, also uncut, punch and washer, scrap, and a small quantity of run of mine mica, the last being sold in bulk. The prices paid for run of mine mica represent the value of the mica as it is taken from the mine; the finished cut mica brings a much higher price, as it is ready to be used and has had a considerable amount of money spent on it. It is obviously inconsistent to add together the value of mica of two classes differing so greatly, yet this procedure is the only one that can at present be followed. For the output of some of the mines an estimate of 10 per cent of the total run of mine mica as uncut sheet has been made.

The domestic output in 1918 came from 10 States, which, grouped in the order of quantity of sheet mica produced, were North Carolina, New Hampshire, Georgia, Virginia, South Dakota, Alabama, Colorado, South Carolina, New Mexico, and Wyoming. As in previous years, North Carolina led all other States both in quantity and in value of mica produced.

Percentages of mica produced in 1918 by different States.

	Quantity.		Total value.
	Sheet.	Scrap.	
North Carolina	57	46	62
New Hampshire	23	23	15
Georgia	13	2	10
Virginia	5	18	7
All other States	2	11	6
	100	100	100

The annual production of mica, by States, for the years 1912–1918 is shown in the following table. Where less than three producers reported output, the figures are omitted, so that no individual production is disclosed. For some of the years, therefore, the figures of production may not be given.

Mica produced by chief producing States, 1912–1918.

a The figures may not be given, as there were less than three producers.

North Carolina produced in 1918 the largest quantity of sheet mica since 1913. Although the quantity was 46 per cent greater than that in 1917, its value was somewhat less, owing in part to the large quantity of punch mica mined in 1918. The increase in production for the State is a notable one. If mining had not appreciably slackened during the last two months of the year, the production for 1918 would no doubt have been double that of 1917. The concentration of mining on sheet mica is shown by the fact that in 1918 the production of scrap mica was less than half of what it was in previous years.

The production of New Hampshire in 1918 was less than that of 1917 and much less than that of 1913. Extensive preparations for increased production, which began to show results in the fall of 1918, would have materially increased the mica output of New Hampshire had the war continued.

Georgia showed the most surprising increase in its production of mica, an increase due to the extensive development of the Thomaston field, where an excellent mica was mined in considerable quantity. If its record-breaking output can be kept up, Georgia will rank as one of the big mica-producing States of the Union. Virginia also increased its production of sheet mica and the value of all mica mined in the State in 1918 was nearly double that of 1917. In both quantity and value Alabama's output was smaller than that of previous years. South Carolina also turned out only a little mica. South Dakota had but one producer, and Idaho reported no production. Small

quantities of sheet mica were obtained from Colorado, New Mexico, and Wyoming, but these were little more than prospectors' samples.

Briefly, then, it may be said that the mica-producing States of this country did not do much more than hold their general average. Under the stimulus of needed production and of high prices, they failed to show that their output could be materially increased.

An attempt was made to obtain the figures of production of sheet mica in 1918 in more detail than formerly. Several of the larger companies have sent in returns in great detail; others have not done so, owing in part to the fact that some mica is not sold by the miner in a sheeted and classified form, and also to the fact that some of the larger companies either do not keep an accurate account of the mica they handle or do not wish to furnish the figures to the Government.

On the basis of the returns received, slightly modified in some reports, the production of sheet mica in 1918, as reported, may be given as follows:

Sheet mica produced in the United States in 1918.

State.	Punch.		Uncut.		Cut.		Splittings.[a]		Total sheet.	
	Quantity.	Value.	Quantity.	Value.	Quantity.	Value.	Quantity.	Value.	Quantity.	Value.

	1,175,500	90,270	333,600	253,840	123,900	382,210	11,200	5,490	1,644,200	731,810

[a] Refers only to splittings actually produced in the mining or sheeting of the mica. A small portion of the uncut sheet is manufactured into splittings. These are not given in this table but will enter into the figures of consumption.

On the basis of 3 pounds of uncut mica yielding 1 pound of cut mica there was a total production in 1918 of about 700,000 pounds of uncut mica, larger than punch, of all sizes and of all qualities. The actual percentages of the different sizes of uncut sheet mica were determined on an aggregate lot of about 150,000 pounds. Owing to the incompleteness of the reports furnished by some of the mica companies it was not possible to calculate the percentages for a larger quantity of mica. These percentages are as follows, applying only to uncut sheet larger than punch: 1½ by 2 inches, 31 per cent; 2 by 2 inches, 25 per cent; 2 by 3 inches, 23 per cent; 3 by 3 inches, 8 per cent; 3 by 4 inches, 5 per cent; larger, 8 per cent. By applying the percentages obtained to the estimated total of 700,000 pounds of uncut sheet mica produced in the United States in 1918 and adding thereto the figures already given for uncut punch, the estimate of the production of sheet mica, given in the subjoined table, is obtained. The figures include all qualities from the clear to the stained. Perhaps a third of the mica could be graded as clear or only slightly stained. It will be noted that this estimate totals about

250,000 pounds higher than that given in a previous table. This is due to the fact that the table of production includes cut mica. In the following table of estimated production by sizes, all the cut mica is reduced to its approximate equivalent (three times) of uncut mica. This procedure increases the total figure of estimated production over that of actual production as given by about 250,000 pounds.

Estimated production of sheet mica in the United States in 1918, by sizes.

	Pounds.
Punch	1,175,000
1½ by 2 inches	217,000
2 by 2 inches	175,000
2 by 3 inches	161,000
3 by 3 inches	56,000
3 by 4 inches	35,000
Larger sizes	56,000
Splittings	11,000
	1,886,000

The percentage yield of cut mica according to use, as given on page 640, applied to the 700,000 pounds of estimated production of uncut sheet mica larger than punch, would represent approximately the following yield of domestic cut mica for 1918:

Approximate yield of cut mica larger than punch in the United States in 1918.

	Pounds.
Cut condenser mica	91,000
Cut electric mica	84,000
Cut stove mica	28,000
Other cut mica	21,000
Scrap from cutting	476,000
	700,000

These quantities would represent a maximum, as the 700,000 pounds of mica include the 1½ by 2 inch size (too small for condenser mica) and include also all grades from the clear to the heavily stained and spotted. The 91,000 pounds of condenser mica may therefore be taken as the approximate maximum quantity of that grade that this country can produce in a year. It is easy to see that the domestic mica was not sufficient to supply the demand for condenser mica, which amounted to many hundred thousand pounds in 1918 and was expected to be nearly a million pounds for 1919, if the military program had continued in full force.

WORLD'S PRODUCTION.

In the report on mica in 1916 several tables were given[1] showing the world's production of mica. Later information has made it desirable to revise the figures of that report, and the tables shown below are probably slightly more accurate. The sheet mica is mostly uncut sheet and splittings. The total world's production of such sheet mica averages annually about 3,000 short tons of an average total

[1] U. S. Geol. Survey Mineral Resources, 1916, pt. 2, pp. 296–300, 1917.

value of $1,000,000 to $1,500,000. This value is considerably increased by the mere processes of splitting, sorting, and trimming. The value of the exported trimmed mica in India, for example, is about three times the value of the crude mica at the mines, and the cut mica or finished product is worth several times the value of the trimmed but uncut mica.

The sheet mica from the United States, as reported, is about 91 per cent uncut sheet, 8 per cent cut sheet, and 1 per cent splittings. That from India is uncut sheet[1] and splittings, the proportions not being known, but estimated as about one-quarter splittings. The Canadian mica is uncut sheet and splittings, the proportion of splittings to sheet not being known, but estimated to be much greater than for the Indian mica. For the other countries the mica reported is essentially trimmed sheet. An approximate idea of the quantity of splittings annually produced in the world can be gained from the table of consumption on page 639.

World's production of sheet mica, 1900–1918, in short tons.

Year.	United States.	India.[a]	Canada.[b]	All other countries.[c]	Total.	Percentage of total represented by production in United States.
1900	228	1,026	(d)	1	.....	.....
1901	180	1,274	(d)	1	.....	.....

1915	277	1,357	209	e 58	1,901	15
1916	433	2,430	604	e 79	3,546	12
1917	638	2,291	583	e218	3,730	17
1918	822	3,062	374	(d)	.....	.....

a The figures for the years 1900 to 1903 are export figures, as no figures of production are available. The figures for the years 1904 to 1917 represent production and not export. The figures of production are probably smaller than the actual quantity of mica produced. The export figures for any one year may be much greater than the figures of production. For example, in 1917 the production was 2,291 short tons but the exports amounted to 3,496 short tons. For 1918 the production was 3,062 short tons but the exports amounted to 3,364 short tons.

b Estimated as one-half of the total reported production of mica in Canada.

c The total reported production of mica for the other countries.

d No figures available.

e Incomplete, as no figures of production are available for some of the countries.

The figures given above under "All other countries" are made up from those contained in the following table:

[1] Although the Madras square-trimmed mica is termed "cut mica" in import schedules, in reality it is uncut trimmed mica.

a No figures available. b Estimated.

The world's production of splittings as separate from trimmed sheet can not be given, as no figures are available. An approximate estimate of such production is given under the heading "Consumption" (p. 639).

The world's consumption of scrap mica is greater than the figures of actual production of scrap mica for grinding. This is due to the fact that a considerable quantity of scrap mica is accumulated in the cutting of the trimmed sheets into regular shaped pieces. The scrap mica so accumulated would be statistically a duplication of part of the figures given under sheet mica. Yet the following figures show more accurately the actual quantity of scrap mica which is used as such, even though part of it was first recorded as sheet mica.

World's total production of scrap mica, 1900–1918, in short tons.

Year.	England.[a]	United States.[b]	Canada.[c]	All other countries.[d]	Total.

1918	(e)	2,703	560	(e)	.....

[a] All derived from the clay pits of Cornwall and Devon.
[b] The reported production plus one-half of the sheet.
[c] Three-quarters of the total production reported One-half of the reported production of mica in Canada is considered as uncut sheet and the other half as scrap. One-half of the sheet probably eventually becomes scrap, giving an estimate for total scrap of three-quarters of the total reported production.
[d] One-half of the reported production of sheet.
[e] No figures available.
f Estimated.

STOCKS.

No large stocks of sheet mica are held in this country. The large miners and buyers of domestic mica at times accumulate more or less mica, but in general the mica is cut up and sold as quickly as it is mined. The small stocks held are mainly only sufficient to take care of the orders coming in and do little more than compensate for the fluctuating production. Small stocks are likewise held by the dealers in imported mica, but it is very doubtful if any of the stocks could be considered in the nature of a reserve.

As the splittings consumed in this country are made up almost entirely from foreign mica, the manufacturers of built-up mica board necessarily have to keep up a small reserve of such splittings. The usual reserves held by such companies are estimated to last from two to six months; in a few exceptional cases a year's reserve is maintained.

Information regarding the stocks of sheet mica available for use, if both the quality and size are not accurately given, is not only worthless but absolutely misleading, for the uses to which sheet mica is put depend wholly on the quality and size of the mica.

From the results of investigation undertaken by the Government it soon became apparent that the available stocks of imported sheet mica would serve for the uses demanded by the war program only for a very short time and that the stocks of domestic mica, although much larger in quantity, would also last for a very short time, as so much of the domestic mica was not of the right quality. Hence it was evident that the United States possessed no available reserve of sheet mica of good quality, that the domestic production could not quickly afford the needed relief, and that the country was absolutely

dependent on imported sheet mica of good quality to meet any materially increased consumption.

Early estimates of the sheet mica required under the war régime because of the rapid increase in Government orders in the manufacture of Government apparatus did not fully anticipate the very rapid growth of the war program and were found to be much too low. The estimates further did not specify whether the sheet mica was to be cut ready for use or whether they referred to uncut mica, even though the ratio of the quantities of cut and uncut mica would be about 1 to 3. A more careful estimate of the Government requirements was therefore undertaken in the summer of 1918, but this estimate, when made, had to be continuously increased, owing to the rapid changes in the requirements of the military program.

The last estimate made in October, 1918, of the requirements of uncut sheet mica, exclusive of splittings, sizes 1 to 6, clear or nearly clear—that is, only slightly stained or spotted—for the calendar year 1919, necessary to the carrying out of Government orders, was that they would amount to at least 1,000,000 pounds, or 500 short tons. At least three-quarters of this would have to be imported muscovite. In addition to this mica of a very good quality, there would be needed a large but unknown quantity of ordinary or stained or speckled mica, used for ordinary electric insulation where the voltage would not be high, and an unknown but large quantity of splittings. Possibly the requirements of all kinds of sheet mica and of splittings would not have been less than 1,000 short tons.

CONSUMPTION.

The consumption of mica in the United States from 1910 to 1918 is shown in the following tables. The first table refers to sheet mica and splittings and all manufactures thereof. The figures are necessarily only approximate, as it is not possible to obtain exact figures. The production of domestic sheet includes all sizes and qualities, cut and uncut. The figures of imported mica do not separate the cut and splittings, and, moreover, as only the value of such mica is given, the quantity has to be estimated. The present figures differ from those given in the report on mica for 1916, and are believed to be more accurate. The export figures represent the total mica exported and are also, in part, estimated.

The second table shows the consumption of scrap and ground mica. The total is made up of the production of domestic scrap attendant on the mining of sheet mica, of the imports of ground mica, and of the scrap mica resulting from the cutting of both the domestic and the imported sheet mica. This quantity has been estimated as one-half of the domestic sheet produced and one-half of the imported sheet, splittings excluded.

Sheet mica consumed in the United States, 1910–1918, in short tons.

[Estimated.]

Year.	Production.	Imports.		Exports.	Apparent consumption.	Percentage of consumption represented by production.	Percentage of world's production represented by consumption in United States.
		Sheet.	Splittings.				
1910	1,238	481	500	10	2,209	56	76
1911	944	164	500	220	1,388	68	44
1912	423	640	355	190	1,228	34	39
1913	850	560	560	170	1,800	47	46
1914	278	180	500	250	708	39	27
1915	277	220	660	45	1,052	26	55
1916	433	350	850	70	1,563	28	44
1917	638	330	1,275	40	2,203	29	59
1918	822	370	913	40	2,065	40	.....
Average	656	366	673	115	1,580	41	.....

The average yearly consumption for the four-year period 1910–1913 was 1,656 short tons, whereas that for the four-year period 1915–1918 was 1,721 short tons, an increase of only 4 per cent. The annual consumption of sheet mica in the United States may therefore be set at about 1,700 tons. About half of this consumption is domestic mica. The greater portion of the imported half consists of splittings.

The average of the figures given in the table showing the estimated consumption of sheet mica allows a further estimate of the quantities of uncut sheet mica annually consumed according to use. The estimates given below were prepared on the reports submitted by the different mica companies in 1918 as to the use to which the mica was put. Expressed in percentages, they are as follows: Of the domestic uncut sheet mica of all sizes, 71 per cent was used for electric insulation, 23 per cent for stove fronts, 2 per cent for phonograph disks, and 4 per cent for other uses (lamp chimneys and canopies less than 1 per cent); of the imported uncut muscovite sheet, excluding splittings, 82 per cent for electric insulation, 5 per cent for stove fronts, 6 per cent for phonograph disks, 4 per cent for lamp chimneys and canopies, and 3 per cent for other uses. The estimated quantities used are shown in the following table:

Estimated average quantities of uncut sheet mica annually used for different purposes in the United States, in short tons.

	Electric insulation.	Stove fronts.	Phonograph disks.	Lamp chimneys and canopies.	Other uses.
Domestic sheet	466	151	13	3	23
Imported sheet	301	18	22	15	10
Imported and domestic splittings	673	0	0	0	0
	1,440	169	35	18	33

These figures refer to the uncut mica. The finished product—that is, the mica which is cut to regular pattern of the required thinness and inspected, with rejection of uncut pieces—will amount to much less, perhaps from a third for the domestic mica to a half for the imported. The figures also represent the total weight of the uncut

mica which is first put to the use specified. In the preparation and cutting of the mica, parts of it will be found unsatisfactory for the use first intended and will be put to a different use—generally electric insulation. For example, if a sheet of uncut mica is selected for phonograph disks, when the actual manufacture of the disks is undertaken it may be found necessary to first peel off a thin film of mica, on account of stains, inclusions, or other defects. This thin film is then utilized in electric insulation. After the phonograph disks have been stamped out of the original sheet, there will remain parts of the mica too small to yield additional phonograph disks but sufficiently large to yield several much smaller washers or disks for electric insulation.

It is not possible, with much assurance of accuracy, to give the quantity of mica cut and ready for use for the different purposes. An estimate, which may have to be considerably modified when more detailed figures become available but which is perhaps as close as can now be made, indicates in percentages the quantities of cut and finished (manufactured) mica annually consumed in the different industries somewhat as follows: For uncut sheet mica, domestic and imported, excluding splittings—for electric insulation 76 per cent, for stoves 17 per cent, for phonographs 3 per cent, for lamp chimneys and canopies 2 per cent, miscellaneous 2 per cent. Including splittings, the percentage consumption of all sheet mica is as follows: Electric insulation 86 per cent (46 per cent sheet and 40 per cent splittings), stoves 10 per cent, phonographs 2 per cent, all other uses 2 per cent.

Estimated average quantities of cut and finished sheet mica annually consumed in the United States, in short tons.

	Electric insulation.	Stove fronts.	Phonograph disks.	Lamp chimneys and canopies.	Other uses.
Domestic sheet	187	76	4	1	8
Imported sheet	167	9	7	7	0
Splittings	673	0	0	0	0
	1,027	85	11	8	8

These estimates suggest that about 45 per cent of the total uncut sheet (excluding splittings) is finally used in the finished form, the remaining 55 per cent becoming only scrap suitable for grinding.

The normal annual consumption of sheet mica (including splittings) in the world before 1914 has been estimated to be about 7,000,000 pounds, or 3,500 short tons, distributed as follows:

Estimated normal annual consumption in the United States of sheet mica (including splittings), prior to 1914, in short tons.

United States	1,700
Germany	800
Great Britain	400
India	400
France	100
Italy	50
All other countries	50
	3,500

The estimated annual consumption and production about balance, and the world thus consumes practically all the sheet mica that is mined. As little or no recovery of mica once used is possible the consumption keeps pace with the production, and it is necessary to produce continuously more and more mica. Such a steady demand is a good incentive to mining, and sheet mica of good quality will always find a ready market, if properly treated, but it is also evident that the natural supply of sheet mica is not inexhaustible and that the time will come when the supply can no longer meet the demand.

No figures are available for the total consumption of mica splittings in the world. The consumption of mica splittings in the United States for the years 1917 and 1918, with an estimated consumption for 1919, are as follows:

Mica splittings consumed in the United States, in short tons.

Origin.	1917		1918		1919 (estimate).	
	Number of consumers.	Quantity (short tons).	Number of consumers.	Quantity (short tons).	Number of consumers.	Quantity (short tons)
India	12	790	13	584	13	663
Canada	10	485	11	329	11	376
United States	7	67	5	64	6	72
South America	.....	0	.....	1	.....	0
	.....	1,342	.....	978	.....	1,111

There are also no figures available showing the actual consumption of scrap and ground mica in the world. The actual consumption is much greater than the recorded production, because a large part of what is recorded as production of sheet mica eventually becomes scrap, being the refuse and trimmings resulting from cutting the uncut mica into cut and manufactured forms.

Ground and scrap mica consumed in the United States, 1910–1918, in short tons.

Year.	Production.	Imports.	Refuse from cutting of domestic and imported sheet.[a]	Consumption.

CONDITION OF INDUSTRY IN 1918.

Early in 1918 it became evident to the manufacturers of radio apparatus and of magnetos that they would have difficulty in obtaining the mica they required. Only a high grade of mica could be used in the condensers that constitute an essential part of these products. A small percentage of the mica so used was mined in the United States, but the bulk of it was imported from India. Canadian amber mica could not be used for this purpose. United States Government specifications, requiring mica, had always insisted on Indian mica, and many manufacturers of mica articles in general showed a marked partiality to Indian mica. It was evident, therefore, that the possibility of a shortage of good-quality sheet mica, largely Indian, was very imminent. To add to the difficulty, the British Government placed all mica coming from India under the control and supervision of the Controller of the Nonferrous Metals Supply of the Ministry of Munitions and no mica was allowed to be shipped from India except to London.

The first organization in the United States looking to Government control of the mica situation was established under the Council of

[1] These figures represent only mica and do not include the clinochlore or chlorite schist produced in Georgia, which in its ground form is very similar to ground mica in its properties and uses. These figures, however, do include some Indian muscovite and Canadian phlogopite. The mica sold in 1918 was also in part derived from production of earlier years. The quantities represented in this table can therefore not be compared with the quantities produced in 1918.
[2] Other than automobile tires.
[3] The largest item is as filler for rubber goods.

National Defense, where a mica committee was early formed with L. W. Kingsley as chairman. Later F. G. Tryon and C. C. Williams were assigned to a study of mica. In the early part of 1918 the subject of mica was placed in the hands of the War Industries Board, where the mica section was organized, with S. A. Tucker as chairman. Conferences attended by Government officials, mica dealers, and consumers—in all about 22 persons—aided all parties in a better understanding of the situation. The mica section was reorganized and placed under the automotive products division of the War Industries Board in the latter part of March, 1918. The personnel of the section at this time was as follows:

H. J. Adams, in charge, War Industries Board;
Maj. E. J. Knabe, U. S. Army, Quartermaster Corps;
Ensign C. G. Grimes, U. S. Navy, Purchase Division, Bureau of Supplies and Accounts, chemical section.

Early efforts of the mica section were directed by Mr. Adams toward encouraging domestic producers in all parts of the country, regardless of the quality of their mica, and numerous samples sent in were submitted to the Bureau of Standards for tests.

An inventory of mica stocks taken by the War Trade Board was of service, although the information obtained was not sufficiently detailed with respect to the size and quality of the mica.

Meanwhile the United States Geological Survey was formulating plans to study the occurrences of domestic mica with the specific object of finding out to what extent the domestic producers could supply the material required. The investigation was begun in May and continued at intervals throughout the year. The Geological Survey also undertook an extensive statistical inquiry as to stock on hand and as to probable production and consumption, having regard to size, quality, and uses of mica, and embodied the information obtained in recommendations as to procedure both in the mining and in the handling of mica. A large correspondence, accompanied by many samples of mica, was handled directly by the Geological Survey, which continued its long-standing practice of directly assisting the producers of minerals both in mining and in marketing their product.

Mr. Adams resigned in May, 1918, and his place was taken by J. W. Paxton. With the resignation of Mr. Paxton in June the section was reorganized under the chemical division of the War Industries Board, with C. K. Leith in charge. The personnel of the section was as follows:

C. K. Leith, in charge;
Paymaster C. P. Storrs, Navy representative;
Maj. M. V. Ayres, Army representative;
W. T. Schaller, U. S. Geological Survey representative;
D. A. Hall, Shipping Board representative;
E. S. Nelson, War Trade Board representative.

Owing to his assignment to other duties, Maj. Ayres resigned in August, and his place as Army representative was taken by Capt. J. N. Magna, of the Aircraft Production Board. The section held meetings regularly on Tuesday of each week. Other Government departments at various times had representatives at the meetings of the mica section—F. B. Silsbee, of the Bureau of Standards; Roger Chauveau, of the Equipment Division, Signal Corps, and others.

As there was no assurance of any immediate large increase in the production of domestic mica of the quality needed for war purposes and as the manufacturers consuming mica on Government contracts insisted that increased importations of Indian mica were an absolute necessity, the British authorities, after a thorough investigation of the situation, were requested through the State Department to release additional quantities of Indian mica.[1] To this request the British authorities acceded on condition that the mica released to this country be controlled by the Government. At the same time the British Ministry of Munitions stated that it had established a schedule of fixed prices for Indian mica and submitted the names of two Government-controlled brokers through whom mica should be bought.

With the idea of regulating prices and satisfying the British authorities, the mica section decided to control the importation of mica. It was agreed that the form of Navy order under the national defense act was the most workable means for exerting this control. Consequently on June 7, a Navy commandeering order on all Indian mica was issued. Under this order the Navy by agreement with the Army and the War Industries Board acted for all interested parties, civil as well as governmental. The purpose of this order was to insure, if possible, an adequate supply of high-grade mica under a stable price schedule and to insure the proper disposal of this material by importers. As a price basis for the Navy order the British fixed prices for mica were adopted. To these prices were added importation expenses, including overhead and incidentals, plus a reasonable profit to the importers. Final payment was left to determination by accounting. At the request of the British Government a list of accredited American importers was furnished to the consul general in London in order that all mica purchased might be accounted for. In October, 1918, new Navy orders were drawn changing the terms from a fixed advance payment and cost accounting on each load taken to a definite price, which was 60 per cent in addition to the price in warehouse in the country of origin or so much thereof as was not in excess of English fixed prices on Indian mica of corresponding grade and quality.

An expert in the mica field was obtained by the Navy in the person of Lieut. Charles P. Storrs, for the purpose of handling the situation. Lieut. Storrs divided his time between the Commandeering Board in New York and the War Industries Board in Washington. He was the actual administrator of the affairs of the mica section and the distributor of mica to Government contractors in need of it. He was able to furnish Government contractors with sufficient material to meet their immediate requirements. There was no conflict as to requirements, the various sizes of mica being used for the manufacture of different appliances. Thus the larger sizes, grades 1, 2, and 3, were required for spark plugs for the Aircraft Production Board for use in Liberty motors; grade 4 was required chiefly for radio condensers for both Navy and Signal Corps radio apparatus; grade 5 was used for magneto condensers for the motor transport service; and the smallest size, grade 6, was also used for spark plugs.

[1] The remaining portion of this section is essentially a copy of the report of activities of the mica section to the director, chemicals division, War Industries Board, which was prepared by C. P. Storrs and D. A. Hall.

Speculation in Brazilian mica resulted in a tendency for prices to rise to a point equal to or higher than the fixed prices on Indian mica of equal or similar grade. For this reason the Navy order was extended on July 29, 1918, to cover Brazilian mica, maintaining the English fixed prices as a basis for payment.

It was the intention throughout that the Navy should simply act as an intermediary between importers and manufacturers and should not use the authority granted by the commandeering order beyond what was necessary to procure and maintain a reasonable quantity of mica as an emergency reserve. For this reason it did not seem necessary to extend the Navy order to domestic mica. It was the intention of the Navy to maintain commandeering orders only until stable price conditions were restored.

An association of importers of mica was formed early in 1918, which at all times contributed its support to the measures undertaken by the Government.

No tangible results had come from the efforts of the mica section under Mr. Adams to increase the production of domestic mica from the established producing districts in spite of high prices and active demand. The idea, however, became current among domestic producers that the Government was in a position to use a much larger part of their output, in some cases even to the extent of financing their enterprises. Considerable pressure was brought to bear to obtain Government aid.

The reorganized section under the chemical division accordingly undertook a careful investigation of the domestic situation in order to determine to what extent, if any, the output of high-grade material might be increased; what means would be necessary to bring about such an increase; and what the chances were for utilizing for Government purposes a greater quantity of the existing output. To this end the domestic producers were invited to submit their ideas on these subjects in concrete form. At the suggestion of the mica section the Association of Southern Mica Miners and Manufacturers was formed at a meeting of producers and dealers in Asheville, on September 3, at which a representative of the section was present. This association was essentially a war-service committee through which problems arising from the industry could more readily be met. The conclusions arrived at were briefly as follows:

1. Any artificial stimulation either in the form of price fixing or financing of mica mines by the Government was not warranted, inasmuch as such action would result in the increased production of the inferior grades of mica, of which there was a plentiful supply, and would not result in a material increase in the quantity of the high-grade material such as was required for Government use.
2. That under existing conditions as to both price and manufacture there was little chance of utilizing a much larger proportion of domestic mica.
3. That the situation warranted assistance to domestic producers with regard to priorities and in retaining skilled labor for the production of mica, as well as in having returned to them as far as possible such labor as had been already drafted.
4. That new enterprises should be encouraged to the extent of giving advice as to the existing conditions and the best means of marketing the output.

The efforts of the mica section so far as the domestic situation was concerned were based on these conclusions. A list of companies to be placed on the preference list for labor priorities was compiled. Many letters were written in answer to requests for information

on the part of prospective purchasers with regard to mica markets, and conferences were held with producers relative to the general situation.

A similar organization of mica producers in the New England States was begun, and it was planned to form eventually a third one covering the western States.

Statistics as to requirements, consumption, and production of mica were early found to be very incomplete. Stocks of imported mica, particularly of the higher grades, were fairly closely determined; but, because of constantly changing specifications and likewise of the variety of sizes and grades of mica involved, progress was made very slowly in obtaining an accurate statistical background for understanding the situation. It became apparent that a complete questionnaire to consumers and dealers was not feasible, and none was attempted. Estimates of requirements of Government contractors were used as the basis for a consideration of war demands. These were amplified by figures as to requirements furnished by the departments of the Army and by the Navy. Lieut. Storrs was at all times in close contact with importers, dealers, and Government contractors, and was thus able to anticipate their needs somewhat in spite of the fact that exact future requirements were not known.

Under the enlarged Army program it became apparent that an increased quantity of mica would be necessary. The situation, though not critical, was becoming increasingly serious when hostilities ceased. Lieut. Storrs was preparing to go to England in order to take up with the British Ministry of Munitions the question of additional allotments.

Questions regarding South American output received careful attention, as this field was providing important additions to our supply of high-grade mica. At one time it seemed evident that higher prices were being offered in Europe for Brazilian mica than were obtainable in this country under the existing Navy order, and steps were taken toward correcting this discrepancy through the inter-Allied purchasing commission in London.

By way of a general summary of results, it may be stated that the establishment of the reorganized mica section found the industry in a chaotic condition, caused largely by the attempt on the part of certain consumers to beat the market, by a threatened shortage of supply from abroad, and by lack of information as to requirements and specifications. A careful analysis of the situation disclosed that the shortage was not as acute as had been supposed. Price regulation and close attention to future supplies of high-grade material were necessary. The Navy order very effectively stabilized the whole situation, and, although not greatly stimulating importation from England, it did stimulate shipments from Brazil, with regard to both quantity and quality of material. Direct Government purchasing abroad, with its consequent effect upon the importing business, did not become necessary, and the cooperation of the importers was at all times cordial. At the same time Government contractors were assured of an equitable distribution of the available supplies to meet their immediate needs. Although the activities of the mica section with regard to the domestic situation did not result in a materially increased supply of mica, certain valuable

results were obtained. Dissatisfaction of producers as to price and other conditions and the belief that they were being discriminated against were very largely dispelled, and their confidence and support were obtained. A clear understanding of the domestic situation made possible conclusions as to the extent to which the material could be counted on to fill war demands.

PRICES.

The prices paid for uncut domestic mica continued to increase throughout 1918 until December, when they dropped to about the prices prevalent in July. The prices paid for domestic mica in the South in 1918 as compared with the prices for similar mica in 1917 were 27 per cent higher for punch, 38 per cent higher for 1½ by 2 inches, 29 per cent higher for 2 by 2 inches, 18 per cent higher for 2 by 3 inches, 13 per cent higher for 3 by 3 inches, and 10 per cent higher for the larger sizes.

The average price per pound of sheet mica produced in 1918 was 45 cents, apparently less than for 1917, 1916, 1915, or 1914, but higher than for any other year. This apparent decrease was due in part to the form in which the figures of production of mica are reported. In previous years some producers reported only their cut mica, which naturally has a higher value than the uncut. For 1918 nearly all the producers reported their sheet mica in the form of uncut mica, which with its lower value would have a tendency to lower the average price considerably. An additional reason for the lower price is that greater effort was spent in 1918 in obtaining the smaller sizes of mica of good quality, as there was no urgent need for the much larger higher-priced sheets. The average price of $246 a short ton for all mica produced is the highest reported and reflected the general increase in the value of mica but was due also to the small production of the low-priced scrap mica. The price of this scrap mica, from $10 to $20 a ton, was the lowest reported since 1906.

The following table shows by years the variations in value and price of the mica marketed in the United States from 1900 to 1918:

Price and value of domestic mica marketed in the United States, 1900–1918.

Year.	Total value.	Average price per short ton of all mica mined.	Average price per pound of sheet mica.
1900	$147,960	$26	$0.20
1901	118,578	50	.27
1902	118,849	75	.22
1903	143,128	73	.19
1904	120,316	84	.16
1905	178,588	112	.17
1906	274,990	125	.18
1907	392,111	110	.33
1908	267,925	92	.24
1909	280,529	56	.13
1910	337,097	64	.11
1911	355,804	80	.17
1912	331,896	91	.33
1913	436,060	71	.21
1914	329,956	82	.50
1915	428,769	101	.68
1916	594,391	122	.61
1917	806,782	198	.59
1918	764,940	246	.45

Average prices per pound paid in the South for rough-trimmed sheet mica of good quality, split and sorted to cut the sizes indicated, 1913–1918.

Size (in inches).	1913	1914	1915	1916	1917	1918
Punch	$0.035	$0.03	$0.04	$0.05	$0.055	$0.07
1½ by 2	.12	.10	.20	.30	.40	.55
2 by 2	.30	.25	.40	.55	.70	.90
2 by 3	.70	.65	.70	.90	1.10	1.30
3 by 3	1.15	1.00	1.00	1.35	1.55	1.75

6 by 6	3.75	4.00	.....	.....	.....
6 by 8	4.85	6.35	6.50	.....	5.50
8 by 10	8.00	8.00	8.00	.....	7.50

The scarcity of Indian mica of good quality led to speculative prices in the spring of 1918, and the Government was compelled to fix the prices of such mica and later to apply the same prices to similar mica from Brazil in order to protect the manufacture of commodities for the Government. The Government fixed prices were based on the English fixed prices plus 60 per cent. These prices were advanced in the summer and again in the fall.

Average prices of Indian sheet mica in the United States, May, 1918, based on the English fixed prices, plus 60 per cent.

Grade.	Quality.				
	Clear.	Part stained.	Second quality, clear.	Second quality, part stained.	Second quality.
6	$0.77	$0.67	$0.58	$0.48	$0.45
5	1.92	1.76	1.70	1.60	1.47
4	3.46	2.75	2.70	2.50	2.11
3	4.62	4.22	4.03	3.84	2.98

The English fixed prices were in effect May 14, 1918. Shortly afterward the Indian mica was more thoroughly classified according to

quality by the British Government, nine different varieties being recognized, and prices were fixed for all sizes.

Prices per pound of Indian mica in the United States, July, 1918, based on the English fixed prices effective in London in July, plus 60 per cent.

Grade.	Quality.								
	Clear Government standard.	Part stained, Government standard.	Second quality, clear.	Second quality, part stained.	Fair, stained.	Ordinary (rust and clay) stained.	Densely stained.	Black spotted.	Soft white.
6	$0.74	$0.59	$0.48	$0.42	$0.38	$0.35	$0.32	$0.29	$0.38
5	1.95	1.78	1.71	1.62	1.49	.98	.59	.48	.88

The increase in price of sheet mica from 1901 to 1918 can be seen from the following table representing the prices paid in London for clear Indian trimmed sheet mica. The prices, in part, represent the sales of certain lots of mica and are not strictly accurate in giving the average values for any one time, but they are sufficiently close to give a picture of the rapidly advancing prices of sheet mica. The prices at which this mica would be sold in the United States would be approximately 50 per cent higher.

Prices paid in London for clear Indian mica, 1901–1918.

Grade.	1901	1908	January, 1911.	September, 1912.	July, 1914.	October 1, 1918.[a]

[b] Grades 5 and 6 were converted into splittings.

IMPORTS AND EXPORTS.[1]

IMPORTS.

The sheet mica, including splittings, imported for consumption in the United States during 1918, as reported by the Bureau of Foreign and Domestic Commerce, was valued at $1,539,482, the highest value recorded by the United States Geological Survey. In 1918 there were also imported 6 tons of ground mica, valued at $1,647.

During the war years imports of mica were received chiefly from England, Canada, India, Brazil, and Argentina. In addition, mica was received in the last six months of 1914 from Germany, China, Guatemala, and Cuba; in 1915 from the Netherlands, Germany, Norway, Guatemala, Japan, and Scotland; in 1916 from France and Scotland; in 1917 from Costa Rica, Guatemala, Mexico, Newfoundland, and Peru; and in 1918 from Guatemala, Japan, British South Africa, China, Mexico, and France. The country named is not necessarily the country of origin of the mica.

Mica imported for consumption in the United States, 1909–1918.

[a] Essentially trimmed sheets.
[b] Includes the Madras square-shaped uncut sheets.
[c] Quantity not reported.
[d] Figures for quantity cover only last six months of 1912.
[1] The statistical information on imports and exports given in this report has been compiled, as in earlier reports, by J. A. Dorsey, of the United States Geological Survey, from data furnished by the Bureau of Foreign and Domestic Commerce, United States Department of Commerce.

The import duty on mica as quoted from the tariff act of October 3, 1913, is as follows:

Mica, unmanufactured, valued at not above 15 cents per pound, 4 cents per pound; valued above 15 cents per pound, 25 per centum ad valorem; cut mica, mica splittings, built-up mica, disks, plates, and all manufactures of mica, or of which mica is the component material of chief value, 30 per centum ad valorem; ground mica, 15 per centum ad valorem.

The figures in the following table refer to mica brought to port of entry and not necessarily entered for consumption in the same year. These figures, therefore, are not comparable to those given in the table of mica imported for consumption.

Sources of imported mica, 1915–1918.

Country.	1915	1916	1917	1918
	Per cent.	*Per cent.*	*Per cent.*	*Per cent.*

[a] For six months, January to June. [b] Not reported.

PROPERTIES.

Mica is unique among minerals in its combination of properties useful to the industries. No other mineral has such a combination

of perfect cleavage, flexibility, elasticity, toughness, transparency, lack of color in thin sheets, nonconductivity of heat and electricity, and resistance to high temperature, to sudden change in temperature, and to decomposition. These properties make mica indispensable in the electrical trade, which consumes most of the sheet mica mined. The enormous expansion of the electrical industry has been furthered notably by the unique properties possessed by mica. These properties enabled mica to play a most essential part in the World War, for the development of wireless telegraphy, of automobile trucks, and of airplanes could have been accomplished only by the use of mica. The recent invention doing away with the need of large and high receiving and transmitting towers for wireless stations is dependent on the use of condensers in which mica is one of the essential components.

Mica possesses other properties than those mentioned which are utilized in the industries. The brilliancy of small mica scales makes this material of value in the decorative arts, and it has been extensively used as a filler of various goods, such as rubber, in the manufacture of patent roofing, and as a lubricant. Thin sheets have also been used as coverings for wounds. More detailed descriptions of the various uses of mica in its different forms is given under the heading "Uses" on page 663.

There are several distinct mineral species grouped together under the term mica, but only a few of them have sufficient commercial value to be mined extensively. Some species of the mica group are of scientific interest only, and some might become of commercial value if it were not that they occur in exceedingly small deposits. The present report refers only to mica that is used as such in the trade and that remains mica in its final application. The only two species, therefore, that are of concern here are muscovite, the ordinary potash mica, also known as white mica, and phlogopite, the magnesian or amber mica.

The different varieties of muscovite have the same chemical composition, but certain varieties have slightly different physical properties which make them specially adapted for particular uses. For example, the best Indian ruby mica is unexcelled for electric insulation, the much harder green mica from North Carolina is specially suitable for stove fronts, and the brown mica from parts of Georgia, on account of its flatness, makes specially fine diaphragm or phonograph mica.

Other micas were mined in the United States in 1918, namely, roscoelite, lepidolite, biotite, and mariposite. Roscoelite has been found only as minute scales and is of value not because of its physical properties but because it is a source of vanadium; hence it is discussed in the chapter on vanadium in Mineral Resources. Another mica mined for its chemical content and not for its physical properties is lepidolite, a compact, fine, scaly mica containing several per cent of lithium. This mica is therefore described in the chapter on lithium minerals in Mineral Resources.[1] Although lepidolite has not been found in sheets of commercial size in the United States, such sheets occur elsewhere and have been mined to a very small extent in

[1] The last Mineral Resources report on lithium minerals is that for 1916.

Canada and more extensively in Australia.[1] Zinnwaldite, another mica, is mined in Europe for its lithium content, but no commercial deposits are known in the United States. Biotite is mined spasmodically in small quantities; no large sheets are obtained, and the mineral is used only in a ground form as a filler and, after ignition, as decorative material. Small quantities of mariposite, a fine-grained greenish mica, are used for ornamental objects and as a pigment in paint. Clinochlore, a micaceous-looking mineral but a member of the chlorite group and not of the mica group, is mined and in a ground form finds application in many of the uses of ground mica.

Mica is sometimes called isinglass. This word has a double meaning; in addition to being applied to mica, it stands for a gelatinous substance, resembling mica in some of its properties, made of the air bladders of certain fish. This substance is soluble in boiling water and burns readily, whereas mica is neither soluble nor combustible.

Cleavage.—Good sheet mica should split easily to perfectly even, smooth sheets, but peculiar irregularities in crystal structure are common to nearly all micas, rendering the cleavage surfaces irregular, striated, or wavy. Tangle-sheet or tangle-foot mica will not split evenly, and ruled mica, to which the names ribbon, wedge, A, hair lined, reeved, fishbone, herringbone, and horsetail are applied, has but little value as sheet mica. Mica which will rupture when cleaved is termed cross grained. Ruled mica, in which the ruling is due to the presence of inclined gliding planes, will also often break up into many small pieces. Wavy, buckled, or corrugated mica is likewise of no value for use as sheet mica.

Only a large deposit, very favorably located with regard to transportation and grinding mill, can be profitably worked solely as a source of scrap mica for grinding. Most mica mines must yield good sheet mica to make the mining profitable. Mica, to be of value as sheet, must yield a rectangle at least 1½ by 2 inches, which must split easily and evenly, be free from cracks, rulings, markings, and all fracture lines, and be reasonably free from inclusions or specks of foreign mineral matter. The size stated is the smallest rectangular size which is salable in the form of uncut sheet; the rough-trimmed mica sheet must be nearly twice as large to yield the rectangle stated. In order to be profitable a deposit must also contain some mica larger than 1½ by 2 inches, and at least a small quantity of the largest sizes of fine quality is almost essential to the successful development of many mica properties. If mica did not usually contain many inclusions of foreign matter and did not have so many physical imperfections, such as cracks, rulings, and holes, there would be no difficulty in obtaining all the mica needed. But, in proportion to the mica mined, there is only an exceedingly small percentage of sheet mica which when finally prepared is of the proper quality to be used in the industries.

Specks and stains.—"Specked" or "spotted" mica contains inclusions of dark materials, mostly some form of iron oxide. The black, brown, or red inclusions of iron oxide—the "specks"—are in some crystals arrayed in straight lines which are either parallel to

[1] A recent communication from the General Foch Mica Syndicate, Kalgoorlie, Australia, was accompanined by clear transparent sheets of lepidolite 5 inches long.

or bisect the edges of the crystal. Specks may be so abundant that the mica is called "black mica," even if the mica itself is nearly colorless. True black mica is biotite or a phlogopite very rich in iron. The specks or spots are extremely thin scales or crystals of iron oxide, which lie between the laminae of the mica but do not penetrate the sheets. Although specked mica is much inferior to clear mica for electric insulation, it can be used in electrical apparatus in which the current has only a low voltage. "Clay-stained" mica owes its unsightly appearance to the introduction of clay and dirt from outside sources. This clay lies between the sheets and may be easily removed by splitting off the thin layer of mica carrying the stain. According to the quantity of specks and stains present, mica is classified as clear, slightly specked or stained, heavily specked or stained, and stained. There are no arbitrary limits to any of these classifications, and mica which may be called clear by one person may be called slightly stained by another. The British Government found it necessary in 1918, in order to fix a fair price on sheet mica, to establish nine different gradings for Indian mica—clear Government standard, slightly stained Government standard, second quality clear and part stained, fair stained, ordinary (rust and clay) stained, densely stained, soft white, spotted, and splittings.

Color.—Muscovite is called clear or white mica. Clear muscovite in thin sheets is almost colorless; in sheets more than one-sixteenth of an inch thick it is amber, yellow, green, yellowish brown, brownish red or "rum," dark red or "ruby" (a piece of the ruby Bengal (India) mica, half an inch thick, is a beautiful ruby-red), smoky, gray, or brown. Muscovite nearly as clear and colorless as window glass is said to have been obtained from Labrador.

Phlogopite in thin sheets is generally yellowish or brownish; in thicker sheets it is yellow, brown, black, or coppery. Three varieties of phlogopite are noted in the trade—clear, transparent soft amber (the most valuable), streaked amber, and opaque hard amber. Phlogopite finds some special uses in electrical insulation because it is slightly softer than muscovite and not so likely to split and crack. It is used as sheets and in built-up mica board, made from splittings. Canada is practically the only producer. Very small quantities have been sent to London, the center of the world's mica market, from Ceylon, Madagascar, South Africa, Japan, and South America.

To a certain extent the color has been used as a means of distinguishing mica from different localities but such a usage is obviously imcomplete and inaccurate. "Silvery white," "yellow," "dark red," or "ruby" applies to Bengal mica, but the term "ruby mica" is also used for mica from Nilgeris (Madras), Brazil, and the United States. "Brown" mica comes from Madras, the United States, German East Africa, and the Transvaal; "green" from Nellore (Madras), the United States, and German East Africa. "Amber" is Canadian phlogopite, and "African amber" is brown muscovite from German East Africa and from the Transvaal.

Hardness.—The differences in hardness shown by mica from different localities are not very great in a strictly mineralogic sense, but they are of importance in the industries, where a relatively very slight variation in hardness may have a considerable bearing on the use of a certain mica. The following scheme of hardness for mica

has been proposed; it is obviously only relative and could no doubt be considerably improved. No. 1 is the softest and No. 7 the hardest.

1. Amber, Canadian.
   (*a*) Soft, clear, transparent.
   (*b*) Medium, hard, streaked.
   (*c*) Hard, opaque.
2. White, Indian.
3. Soft green, Madras.
4. Ruby, Indian.
5. Hard green and brown, Madras.
6. Green, brown, and yellow, East African.
7. Green, United States.

Other properties.—The physical properties that make mica of commercial value are developed to different degrees in the different kinds although the variations are only slight. Biotite is not nearly so elastic as muscovite, phlogopite is a little softer than muscovite, and lepidolite fuses at a much lower temperature than muscovite. Even muscovites from different localities have slight variations in hardness, elasticity, and electrical resistance. This variation is said to be related in part to the color of the micas. Green muscovite from the United States is said to be the hardest of all micas, and the Indian ruby mica, is said to have the greatest dielectric strength or electrical resistance.

Good sheet mica should be so flexible that a sheet a thousandth of an inch thick can readily be bent into a cylinder ¼ inch in diameter without showing any cracking.

Classification.—The standards of classification of sheet mica with regard to quality and to size differ not only in different countries but even in different parts of our own country. Although the classification applied to domestic mica is fairly uniform, the absence of quantitative limits in the description of quality makes it difficult to define exactly a certain lot of mica. Three grades are generally used—clear, slightly spotted or stained, and heavily spotted or stained. The term "clear" is often used for mica which is anything but clear. It is this loose use of the term which has prejudiced many dealers against domestic mica. Calling mica "clear" when it is full of specks and stains is certainly extending the word "clear" far beyond its true meaning.

The basis of size classification of rough-trimmed uncut mica in the United States depends on the dimensions of the clear and usable circle or rectangle which can be cut from the rough-trimmed piece of mica. Punch mica will not yield a clear rectangle as much as 1½ by 2 inches but should yield a round disk of usable mica 1½ inches in diameter if stained and 1¼ inches in diameter if clear. Circle mica will yield a somewhat larger circle and is considered as lying between punch and the smallest rectangular piece. Circle mica should contain a usable disk nearly 2 inches in diameter. The smallest rectangular uncut mica, is 1½ by 2 inches. The next size is 2 by 2 inches, followed by 2 by 3, 3 by 3, 3 by 4, 3 by 5, 4 by 6, 6 by 6, 6 by 8, 8 by 10, and larger. A piece of uncut, rough-trimmed mica, classified as 2 by 3, should be large enough to yield a clear and usable rectangle 2 by 3 inches, the actual dimensions of the piece of mica itself being much larger, often nearly double the dimensions given. The dimensions of a well-trimmed piece of mica should not in general

be more than 1½ times the dimensions of the contained usable rectangle. A 2 by 3 trimmed mica sheet should therefore not measure much more than 3 by 4½ inches.

The Canadian amber mica is classified on a similar basis, namely that of the contained usable rectangle, the sizes, which are somewhat different from those used for domestic mica, being 1 by 1, 1 by 2, 1 by 3, 2 by 3, 2 by 4, 3 by 5, 4 by 6, and 5 by 8. For both domestic and Canadian mica, each class includes the size mentioned and all larger sizes up to but not including the next size. The 2 by 2 size would therefore include mica containing from 4 up to but not including 6 (2 by 3) square inches. A piece yielding 5 square inches (2 by 2½) would be classed as 2 by 2.

The Indian classification does not use the size of the rectangle obtainable, but the area of usable mica in the sheet. To certain areas arbitrary grade numbers have been assigned. For example, grade 5 must contain from 3 to 5⅞ square inches of usable mica, but obviously there must also be set at least a minimum width to the usable part, as a piece measuring one-fourth inch by 16 inches would contain 4 square inches but would not be classed as grade 5. The limiting sizes of the rectangles, which a piece of mica graded on the Indian classification must contain, have therefore been established by convention. The following table shows the Indian scheme of grading. The approximate corresponding sizes used in the domestic classification are also added.

Grading of Indian mica.

Grade.	Areas of usable mica (in square inches) based on rectangular sizes.	Sizes of rectangles that can be cut (in inches).				Approximate corresponding domestic sizes (in inches).
		Width.		Length.		
		Minimum.	Maximum.	Minimum.	Maximum.	
6	Less than 3					Punch.
5	3 to 5⅞	1	2	2	2½	2 by 2.
4	6 to 9⅞	1½	2½	2½	3	2 by 3. 3 by 3.
3	10 to 14⅞	1½	3	3	4½	3 by 4.
2	15 to 23⅞	1½	3½	4½	6	3 by 5.
1	24 to 35⅞	3	5	5	7	4 by 6.
A–1	36 to 47⅞	4	6	7	9	5 by 8.
Special	48 to 59⅞					6 by 8.
Extra special	60 to 71⅞					8 by 8.
Extra extra special	72 and more.					8 by 10.

The differences in the properties of mica and in the uses to which mica of different sizes is put cause the mica to be prepared in a number of different forms, which are described in the following section.

Crystals of mica as mined are rough blocks, hexagonal in shape if complete, but more commonly in irregular shaped masses, showing one or more crystal sides. After being freed from adhering rock, the mica blocks are split into thin sheets, which are roughly trimmed around the edges by the fingers or a knife—"thumb trimmed" or "knife trimmed"—and then graded for size and quality. The proportion of finished sheet, ready for use, obtained from the rough blocks is small, rarely being as much as 10 per cent. The remainder, the waste, is scrap mica suitable only for grinding.

Through the courtesy of four of the larger mica companies, enough detailed information has been furnished to the United States Geological Survey to enable it to calculate the percentages of sheet mica obtained. The total quantity of mica concerned is large enough to give the figures considerable value. They refer only to mica mined in the years 1916, 1917, and 1918, in North Carolina, Georgia, and Alabama, chiefly North Carolina. The total quantity of mica—all mined because of its sheet content, on which the computations are based—was about 2,500,000 pounds.

Percentage yield of mica mined by certain companies.

FORMS.

In the various stages of preparation or manufacture from the mine to final consumption mica appears in several forms representing different degrees of work or manufacture. These forms may be grouped under three general classes—mine run, sheet, and scrap. The mine run is the form in which the mica is obtained from the mine; it comes in rough blocks from which the adhering rock has been removed. These blocks do not always give an indication of the quality of the mica throughout the crystal and may contain much good sheet or may be so flawed as to be of value only as scrap for grinding. These mine-run blocks of mica are also called "books," and the terms "book mica" or "block mica," applied to domestic mica, are synonymous with "mine-run" or "run-of-mine" mica. The term "block mica" unfortunately has also been applied to imported sheet mica. Very little mine-run mica is sold as such in the South, but in parts of New Hampshire and in the West, particularly in South Dakota and in Idaho, much of the mica is sold by the miner as mine-run mica.

When these blocks of mine-run mica are cleaved or split into thin sheets, about one-sixteenth of an inch in thickness, the mica is called "sheet." Several classifications are used for sheet mica, dependent on the extent and character of the trimming and the uses for which the mica is intended. In trimming the sheet mica the broken and flawed parts of the sheets, mostly near the border, are broken and cut away, leaving an irregular-shaped piece from which a regular pattern may be cut. Thumb-trimmed mica has the loose and imperfect parts broken off by the fingers alone; knife trimmed has additional imperfect parts cut away with a knife. "Rough trimmed" is an indefinite term, perhaps representing a stage in the preparation of mica intermediate between thumb trimmed and knife trimmed. Rough-trimmed mica is also termed "sheet mica." Further modifications are introduced by such terms as "close trimmed." Most of the domestic mica, when first sold, is rough trimmed or poorly knife trimmed. Sickle-trimmed mica is closely knife trimmed, the large knife used being called a sickle. It is the form in which the Indian and other foreign mica is first sold. Sickle-trimmed mica, also called "Indian trimmed," is much closer trimmed than domestic knife trimmed and rarely contains any mica with cracks or important flaws, whereas the domestic knife-trimmed material still contains many imperfections, although the most prominent have been cut off. Sickle-trimmed mica, although irregular in shape, approaches a rounded rectangle. Mica from Madras, India, is cut with a shear into roughly square patterns and is called "shear trimmed" or "Madras trimmed." In shear-trimmed mica the cut edges are normal to the cleavage plane, whereas in sickle-trimmed and knife-trimmed mica these edges are beveled. Foreign sheet mica is also called "plate" or "block." Sheet or split mica is also technically termed "uncut" or "unmanufactured."

Sheet mica is also classified according to the uses to which it is put. Condenser mica must be clear ruby, colorless, or greenish, must split easily and smoothly into films as thin as one-thousandth of an inch, must be free from cracks, holes, foreign substances, stains, spots, smoke, and sheets, and must be plane and smooth, free from waves, wrinkles, reeves, rulings, or knots. Uncut condenser mica to cut any particular size must not be larger than one and one-half times that size each way. Cut but not split condenser mica is cut into regular sizes, 2 by 2 or 2 by 3 inches, which are slightly larger than the thin sheet actually used in the condensers. From this cut mica the condenser film is then punched out in the shape and size used. If cut and split, the individual pieces are from 0.001 to 0.003 inch thick, with an allowable variation of only 0.0005 inch. If cut or punched into the required shape, split to the necessary thinness, and carefully inspected, the mica is called condenser film mica. The cut edges of the films must be smooth, and the finished film must of course be free from all defects and cracks. For wireless outfits each film must withstand 20,000 volts. For magneto condensers no such high-voltage resisting test has to be made, but each film must be free from cracks or other defects. Such "film mica" is very different from the thin splittings used in the manufacture of mica board. These irregular-shaped splittings are sometimes also called films. It has been estimated that on an average it takes from

2 to 3 pounds of trimmed Indian or cut domestic mica (or double the quantity of uncut domestic mica) to yield 1,000 acceptable condenser films. By careful selection it has been possible to obtain a pound of cut films from 5 to 6 pounds of domestic uncut sheet mica.

Phonograph or diaphragm mica is also a variety of very high grade. It must be free from all imperfections, such as rulings and cracks and inclusions of other minerals, must split well and even, must be clear and transparent, and must also be flat, this last feature being an essential character of diaphragm mica.

Mica for lamp chimneys and canopies must be clear, split easily, and be very flexible. Indian mica is the best, and Brazilian mica is also good. Very little domestic mica can be used for this purpose.

For stove fronts a nearly clear mica, hard and rigid, is most desirable, and much of the North Carolina mica, especially the greenish, is well adapted for this use.

The finest, clearest, and hardest mica is also called "bulkhead mica," although this term is not commonly used by the producer of domestic mica. It is of about the same quality as diaphragm mica. Mica that is essentially clear and has only a few spots or stains is called "stove mica." It is the ordinary variety of clear mica, although much mica that contains altogether too many imperfections is called "stove mica." A distinction is sometimes made as follows: Stove No. 1 is essentially "clear" and free from specks, but is not entirely free from air bubbles; stove No. 2 has some discoloration and a few black spots, enough to be called "slightly spotted." Electric mica is spotted or slightly stained, but not enough to prevent its use in general electric insulation. Spotted mica contains too many specks or inclusions of iron oxide to be suitable for high-voltage insulation.

Splittings are the very thin sheets or films of mica which are split from the smaller sheet mica. The excellent cleavage possessed by mica allows the material to be easily split into these thin films. The splittings are about one-thousandth of an inch thick, are irregular in shape and outline, and may contain a small quantity of flaws. They are so thin that a bunch of them feels like a mass of crumpled tissue paper. A small quantity of such splittings accumulates in the sheeting and trimming of the mine-run mica, but most of them are made by splitting up the smaller sheets of mica, especially the stained or spotted mica. In India, where most of the splittings are produced, the work is largely done by women and children. A delicate touch is required, and children make the best splitters. The mica sheets are split either with a small knife or with the thumb nail, which is purposely allowed to grow long. From 2 to 4 pounds of splittings a day is considered a good output. In Canada, where the splittings are made from amber mica, they are known as "thin-split mica." In the United States the domestic splittings are also called "slittings," "skimmings," or "films."

After the sheet mica has been all split into films of uniform thickness, they are reassembled into a large plate, being fastened together by means of an insulating cement under the application of heat and pressure. The thin films or splittings, in addition to being of uniform thickness, must have no thick edges or corners and must be free

from all inclusions of hard mineral grains, so that the final built-up plate can be compressed to a uniform thickness. The splittings are laid irregularly one on the other either by hand or by specially devised machines. Shellac is the binder commonly used; it must be spread evenly and thinly over all the splittings; when the mica board is finally compressed and ready for use,[1] it should have uniform thickness and density, very low compressibility, and a binder or cement content of 3 to 5 per cent, preferably the lower figure, and should show almost no shrinkage, slipping, or oozing of cement. The standard size of the board is 18 by 36 inches. Muscovite and phlogopite or amber-mica splittings are both used, either separately or in various mixtures, to form boards with slightly different properties.

The built-up mica board is used chiefly for commutator segments and end rings and, in special shapes and sizes, either cut or molded, in dynamos, motors, and transformers.

The mica boards manufactured by different concerns have been given special trade names as follows:

"Micanite" is a term applied by the Mica Insulator Co., of Schenectady, N. Y., to a manufactured mica board or plate, built up by successive layers from many small thin films of mica, which, after being dipped into and cemented with shellac, are then subjected to pressure under heat to dry out the shellac. These large sheets are then milled to the requisite thickness and made suitable for many electrical purposes.

"Micabeston," which is similar to micanite, is manufactured by the American Mica Co., of Newton Lower Falls, Mass. Several varieties are made, one of which becomes flexible when heated and rigid when cold and is used for insulation in field coils, transformers, armatures, etc., where high heat is not generated; another variety remains rigid under a high heat and is used in commutators of generators and motors.

"Micabond," made by the Chicago Mica Co., of Valparaiso, Ind., is also similar and is made in varying qualities with different properties, depending on its use.

In these manufactured mica sheets a number of different substances are used as binders in addition to shellac, chiefly paper of various grades (Japan tissue, manila, rope, fish), muslin cloth, rubber, and gutta-percha.

The greater part of the domestic splittings consumed are purposely made directly from the uncut sheet. Domestic splittings also accumulate incidentally to the splitting of the mine-run blocks of mica into uncut sheet, and in the cutting of sheet into definite forms, as it is often necessary to skin a thin sheet of mica before cutting, so as to remove a particular stain or nest of specks.

The Canadian or amber splittings are either imported as such, being obtained in the same way as the domestic splittings, or else are manufactured in this country from imported uncut sheet. It is believed that the great bulk of the amber splittings consumed are imported as such.

[1] Much of the information here given is abstracted from a booklet, "The insulation of commutators," published by the Mica Insulator Co., 68 Church Street, New York.

Some Indian splittings are manufactured in this country from the uncut sheet, and some accumulate in the cutting of the mica sheets, but nearly all the Indian splittings consumed are imported as such.

The waste mica resulting from the trimming and cutting of sheets, as well as the mica mined that does not contain any sheet of value, is called scrap and is suitable only for grinding. Scrap mica, as it comes to the grinding mill, is of various sizes and, unless formed exclusively from the waste of cutting, contains small inclusions of rock, chiefly quartz and feldspar. The scrap mica is ground into various sizes and sold as ground mica. A very coarsely ground mica used in wrapping tarred roofing paper is called "bran."

The forms of mica as described are summarized below.

- Mine-run.
- Sheet:
  - Uncut or unmanufactured:
    - Condition:
      - Thumb-trimmed.
      - Rough-trimmed.
      - Knife-trimmed.
      - Close-trimmed.
      - Sickle or Indian trimmed.
      - Shear or Madras trimmed.
    - Use:
      - Punch.
      - Condenser.
      - Stove.
      - Electric
      - Diaphragm.
  - Splittings:
    - Loose, as such.
    - Manufactured board.
    - Tape and other forms.
  - Cut or manufactured:
    - Washers.
    - Film or condenser.
    - Stove.
    - Electric.
    - Phonograph disks.
    - Manufactures of built-up mica board.
    - Other manufactures of splittings.
- Scrap:
  - Unground.
  - Ground.

Special trade names have been given to different forms of micas, as follows:

"Rimco" is mica ground by a nonmetallic process by the Richmond Mica Co., Richmond, Va., for use as a tire powder. It is also used by manufacturers of oils and lubricating greases.

"Micamima," prepared by the Crawford Mica Co., of Crawford, Nebr., is a coarsely ground mica used in the manufacture of concrete facing material; mixed with other minerals it is used to give the effect of natural rock, and it may be used for different decorative purposes.

"Micolith," or "micholithic," prepared by the Texas Mica Co., of Pecos, Tex., is another similar product used to give the effect of natural rock to concrete facings.

"Tungash," as the Denver Mining & Manufacturing Co., of Denver, Colo., calls its product, is a bronze-colored, metallic-looking material of value for decoration. The crude biotite mica, altered

and hydrated, has a dull greenish-black appearance when mined. On being heated it expands to a light product, which has a rich golden-bronze color and a decidedly metallic luster.

"Silberglimmer" (silvery mica) is muscovite which has been heated to a sufficiently high temperature to make it softer and opaque and silvery in appearance. It is also known as annealed mica and finds a use in certain parts of electric apparatus.

"Clinomica" is the name given by the American Mica Co., 52 Broadway, New York, to its ground clinochlore, a micaceous mineral of the chlorite group. Clinomica possesses essentially the qualities of ground mica, and is used as a dusting material in the rubber and composition-roofing industries, for paints, cements, lubricants, molded electric insulation, and as a filler for various products.

USES.

The different uses to which mica is put depend on its form—whether in sheets or as ground mica. Sheet mica is used as an insulator in the electrical industry, for glazing, and to some extent for other purposes. Ground mica is used chiefly in patent roofing, in the decorative trades, for lubrication, as a filler, and for annealing.

Sheet mica finds its greatest use in the electrical industry, where an insulating, noninflammable, resistant material is necessary. In thin films it is used extensively in condensers for magnetos and wireless apparatus. It is used as an insulator in the form of sheets, washers, and tubes in dynamos and in numerous electric fittings and appliances, such as electric heating devices, electric-light sockets, spark plugs, insulators, guards in rheostats, fuse boxes, and telephones. Flexible cloth and tape, partly made of or covered with mica, find varied uses in electrical apparatus. Sheet mica is also used for glazing the fronts of stoves, for furnace sightholes, for screens in front of highly heated material, for optical lanterns as a retarder of heat waves, for making lamp chimneys and lamp shades, and for military lanterns. It is also used in special spectacles, in motor goggles, in sand blasting, in sightholes of diver's helmets and smoke helmets, in compass cards, in gage fronts, in windows where glass would be broken by heavy shocks or by vibrations, as in the conning towers of warships and of submarines, in lantern transparencies, and for mounting soft natural-history objects preserved in alcohol. Mica diaphragms are used extensively in phonographs and other sound-producing devices.

Large numbers of sheets of mica are used in India as the material on which pictures and portraits are painted, the mica being very durable, unaffected by heat or by dampness, and resistant to attacks of insects. Sheet mica is also used in India for ornamentation, such as inlaid work, for which a peculiar silvery mica is specially adapted, and for tassels, flowers, toys, and banners.

Sheet mica was an important and essential war mineral through its use as insulator in electric apparatus, especially in condensers, for magnetos and wireless apparatus, and for spark plugs; as windows and for other uses where a transparent, noninflammable, nonshattering material is necessary, as in automobile goggles; and as coverings for wounds.

First-quality clear ruby mica had to be used in the manufacture of radio-condensers, magneto condensers, and spark plugs for airplane and automobile truck engines. A poorer quality was used for blocking the condensers and for general electric insulation.

Most mica splittings are consumed in the manufacture of built-up mica board used for general electric insulation, but the splittings also find application as such in making mica tubes for spark-plug cores and other insulating uses, wrappings for wire coils, and insulating tape.

Ground mica is used for decoration in wall paper, to which it gives luster and brightness; in fancy paints, ornamental tiles, and concrete. A mixture of ground mica and powdered aluminum is said to make a good rust-preventing paint, the ground mica being much cheaper than aluminum. The color and luster imparted by mica in certain paints may help to give a deceptive value to the object painted. Ground mica is useful because of its heat-resisting qualities, in the packings on railroad cars to prevent hot boxes, in pipe and boiler coverings, and in fireproof paints and coverings. Because of its heat-resisting qualities, it is used in making both solid and pneumatic rubber tires. It is also used by rubber manufacturers to preserve the rubber and as a finishing pigment. Ground mica is an essential component in some patent roofing material and is used in making molded mica (ground mica mixed with shellac) for electric insulation and in calico printing; as an absorbent for nitroglycerin in the manufacture of "mica powder"; in annealing steel; to a large extent as a lubricant for wooden bearings, or, mixed with oil, as a lubricant for metal bearings; in the manufacture of automobile treads on new tires, as well as in repair stock; in tire powder; as a filler for rubber goods; and for various other products. Tar and other roofing papers are coated with coarsely ground mica to prevent sticking when they are rolled for shipment. A possible value of ground mica as a chemical source of potash salts has been suggested, especially its direct application to the soil as a fertilizer.

In India ground mica is used for processional ornaments, such as lamps, pottery, curtains, cloth, and tinsel decorations on fans, and in buildings, especially in temples and palaces. It is also used for heat insulation in coverings for pipes and on roofs. Ground to a coarse powder and mixed with starch, it is so applied to cheap cotton cloths as to give them an attractive sheen. Large quantities have also been employed there for medicinal uses—an application which, fortunately, has not extended beyond its country of origin.

The percentages of different forms of mica consumed for different uses are given in the section headed "Consumption" on page 639.

The uses of mica may be summarized as follows, the classification being based on the physical property of greatest importance:

Electric insulation: Sheets, films, mica board, washers, mica cloth, and tape, for dynamos, condensers, telephones, light sockets, spark plugs, and innumerable other electric appliances. Ground mica mixed with shellac is molded into various insulating forms.

Heat insulation: Screens in front of highly heated material, as retarder of heat waves in optical lanterns, and in electric heating devices. Ground mica is used as pipe and boiler coverings, in annealing steel, and fire-proof paints and coverings.

Transparency: Glazing the fronts of stoves, for furnace sight holes, lamp chimneys, lamp shades, military lanterns, lantern slides, spectacles, sight holes

of diver's helmets, compass cards, gage fronts, in windows where glass would be broken by heavy shocks or vibrations, and as coverings for wounds.

Resonance: Phonograph diaphragms and various sounding devices (submarine detectors).

Decoration: Sheets of mica form the material on which pictures and portraits are painted and for inlay work. Ground mica is used extensively for decoration in wall paper, processional ornaments, fancy paints, ornamental tiles, and concrete.

Lubrication: For wooden and metal bearings, tire powder.

Filler: Patent roofing material, rubber goods, buttons, absorbent for nitroglycerine, and various other products.

Miscellaneous: Calico printing, to prevent sticking of tar papers, medicinal uses (India only).

A recent classification of the uses of mica, based on their relative importance, is as follows:

Essential uses: Electric insulation—films, sheets, washers, splittings, and built-up mica board.

Less essential uses: Stove front, lamp chimney and shades, electric heating devices, pipe and boiler coverings, roofing material, annealing steel, lubricant for wooden bearings.

Nonessential uses: Phonograph diaphragms, decoration, lubricant for metal bearings, filler for rubber and various other materials.

SUBSTITUTES.

Some of the uses of mica are highly essential, others have developed more from the need of finding an outlet for those forms of mica whose production is incidental to the preparation of the leading commercial product, cut sheet mica.

It can not be said that ground mica has any essential use. For certain applications ground mica may be superior to other substances, but for every one of these applications—insulation, decoration, lubrication, annealing, coating, and filling—other materials can be and are used. As a few examples may be mentioned the substitution of asbestos in insulation, of chlorite schist in decoration, and of graphite in lubrication.

As given under the heading "Consumption," the uses to which uncut sheet mica (domestic and imported), including splittings, is put, average about as follows: For electric insulation, splittings 40 per cent and sheet 46 per cent, a total for electric insulation of 86 per cent; stove fronts, 10 per cent; phonograph diaphragms, 2 per cent; lamp chimneys, canopies, and all other uses, 2 per cent. Electric insulation covers a wide field and requires very different kinds of mica. The use of splittings in the manufacture of built-up mica board has reached a large development, the average annual consumption of splittings being greater than that of sheet mica.

There is no known successful substitute for mica splittings or for the manufactured built-up board made therefrom.

Attempted substitutes for mica have been of two kinds—either a compressed paper product specially treated, or bakelite, or a similar product. The compressed paper products are either oiled paper in very thin films, which may be built up into any desired thickness, or specially manufactured products, two of which have been given special names.

Micarta is an artificial mica product developed by the Westinghouse Electric & Manufacturing Co., of Pittsburgh, Pa., and is in-

tended to take the place of hard fiber, glass, porcelain, hard rubber, built-up mica board, rawhide, molded compounds for use in commutators, bushings, brush-holder insulation, noiseless gear blanks, conduits for wiring, spools for spark coil and magnet windings, wireless-coil separators, and water-meter disks. Micarta is a tan-colored, hard, homogeneous material that can be sawed, milled, turned, and threaded. Thin sheets can be punched, and it is claimed that it will not warp, expand, or shrink beyond very small limits. Two grades of micarta are made. One, known as bakelite micarta, is infusible and will resist heat to a point at which carbonization of some of the ingredients takes place. It is insoluble in nearly all ordinary solvents, such as alcohol, benzine, turpentine, and weak acid and alkali solutions.

Pertinax is a product developed by Germany in consequence of its shortage of mica and was used specially for high-tension condensers. Part of the inefficiency of German airplanes has been ascribed to the use of pertinax in place of mica, often with disastrous results. Pertinax is a compressed-paper product which can be turned, stamped, sawn, cut, and drilled like wood. It will withstand high pressure, is not affected by hot oils, and begins to be destroyed only at about 200° C. Its puncture voltage is reported to be about 25,000 volts per millimeter.

Bakelite, a synthetic product made from carbolic acid and formaldehyde, is said to be a promising substitute for built-up mica board, especially as it may be poured into a piece of apparatus and thus molded right in place into the proper shape. But although the future may show some increase in the use of bakelite as a substitute for mica, at present mica splittings and their manufactured board have no satisfactory substitutes.

A product is also manufactured from kelp, which is hardened by treatment with formaline and can be pressed into any shape, turned, and highly polished. It possesses a high insulating quality, but obviously such material is not suitable for insulation where a thin film has to be used.

Oiled paper and compressed paper products are also used as substitutes for sheet and film mica, but only in certain places, and in general there is no satisfactory substitute for sheet mica used in electric insulation. As electric insulation accounts for 86 per cent of the sheet mica and splittings consumed and there is no satisfactory substitute known for them, it is evident that sheet mica must be considered an essential industrial mineral. For the remaining 14 per cent of applications of mica, substitutes can be used, for special kinds of glass will do for stove fronts and lamp chimneys, and many substances can be used for the reproducing diaphragm in phonographs.

FUTURE SUPPLIES OF MICA.

INTRODUCTION.

The future development of deposits of mica depends in part on the answer to the question as to whether or not the substitutes for mica will ever completely replace the natural mineral. So far as known there is no satisfactory substitute for sheet mica used in elec-

tric insulation, which consumes 86 per cent of the sheet mica and splittings produced. During 1918 the need for sheet mica of good quality was very urgent and there was an unusual opportunity for the development of substitutes for it. The fact that none were found that satisfied the requirements indicated the improbability of any successful substitute being found for many years, if indeed any is ever found. The operator of any deposit of sheet mica therefore need not fear the competition of any artificial substitute, and with the growing applications of electricity, requiring insulation against ever-increasing voltages, the market for sheet mica of good quality must necessarily continuously increase.

Sheet mica of commercial value is found practically only in certain dike rocks known as pegmatites. Muscovite sheet mica is obtained only from quartz-feldspar pegmatite dikes, phlogopite at present entirely from the mica-calcite-pyroxene-apatite dikes, the true geologic genesis of which seems to be not entirely understood, but which are more or less intermediate in mineral character between pegmatite dikes and mineral veins. At a few places phlogopite sheets of commercial size are found in country rock such as serpentine and limestone, but all the commercial sheet mica is extracted from dikes. Muscovite can be used wherever phlogopite is used, although it is not so satisfactory for some uses, but phlogopite can replace muscovite in only a few of its applications. The following paragraphs refer almost exclusively to muscovite.

The necessary geologic conditions for the formation of sheet muscovite are the presence of numerous quartz-feldspar pegmatite dikes cutting metamorphic or crystalline rocks.

The geologic preservation of sheet mica demands the absence of folding and minute faulting, after the formation of the pegmatite dikes, for such movements would crumble and bend the mica sheets and render them worthless. Folding and faulting of mica-bearing rock develops in the mica sheets injurious properties such as ruling, which causes the sheets to break up into many small pieces, and wavy, buckled, corrugated, and other structures which prevent the easy splitting of the mica and leave the sheets with irregular, striated, wavy, or adhering surfaces. A deposit of such mica can not usually be profitably exploited, for the successful development of any mica deposit is generally dependent on its output of good clear sheet, as the scrap or mica suitable only for grinding—and this is all that ruled, buckled, and irregular mica is good for—is only an incidental by-product.

There are only a few regions where the earth's crust seems to be specially stable and to have withstood the folding and faulting earth movements for a long period of geologic time. The geologically old and stable peninsula of India, which has remained a firm solid mass since paleozoic time abutting against the crumpled and sheared Himalaya Mountains, the great stable mass of central and eastern Africa, and the American Piedmont, abutting against the Appalachian Mountains, are such regions. It is therefore obvious why commercially profitable deposits of sheet mica are extremely rare, although mica itself is one of the commonest of minerals, forming a part of nearly all rocks.

To be commercially exploitable mica deposits must occur under favorable geologic conditions. Any deposits covered by alluvium, lava, or other rock formations would be effectually concealed from the prospector, for sheet mica underground can not be prospected for by drilling or by its effect on the magnetic needle. Other commercial features are of course of the greatest moment in affecting the success of any mica-mining project. Such features involve questions of labor, transportation, grading and packing, and market.

The chief producers of sheet mica are India and the United States (muscovite) and Canada (phlogopite). These three countries furnish about 98 per cent of the world's output. No country other than Canada produces any material quantity of phlogopite, but at several widely separated places outside of India and the United States deposits of fine sheets of muscovite occur and have been mined for several years. The most notable of these deposits are in the former German East Africa, Brazil, and Australia. The countries producing sheet mica may be placed in four groups according to their relative output. The first group, which absolutely dominates the mica situation to-day, comprises, as stated, India, the United States, and Canada. The second group includes those countries which have yielded small quantities of excellent sheet mica but are not sufficiently developed to show their potential productiveness, though they nevertheless suggest that in time they may become producers of great importance. This group includes German East Africa, Brazil, Australia, and possibly western Canada (British Columbia). Before 1900 their production was practically negligible. From 1906 (the first year for which figures of production are available for all the countries) to 1913, inclusive, their combined production amounted to 3 per cent of the world's output. For 1917 their combined output was estimated to be about 10 per cent of the total. The third group comprises the smaller producing countries, which have turned out some good mica for many years, but either they have not developed into important producers or else information about their mica deposits is so meager that their relative importance can not now be judged. The countries included in this group are Argentina, the Union of South Africa, Guatemala, Ceylon, and Madagascar. Perhaps the first two and possibly some others should be placed in the second group. The fourth and last group contains those countries from which sheet mica has been reported but which no longer produce it or about which definite knowledge of the quality and occurrence of the mica is lacking. These countries are Norway, Peru, Mexico, Russia, Chosen (Korea), China, and Japan.

Grouped according to continents, with their relative rank in importance, according to the four groups described, the sheet-mica producing countries are:

	Group.
North America:	
United States	1
Canada	1
Guatemala	3
Mexico	4
South America:	
Brazil	2
Argentina	3
Peru	4

	Group.
Europe:	
Norway	4
Africa:	
German East Africa	2
Union of South Africa	3
Madagascar	3
Nyassaland Protectorate	3
Rhodesia	4
Protectorate of Southwest Africa	4
Kamerun	4
Asia:	
India	1
Ceylon	3
Chosen	4
Siberia	4
China	4
Japan	4
Australasia:	
Australia	2
New Zealand	4

Politically, the United States and Great Britain control essentially the entire output of sheet mica, the only mica-producing countries not under their sovereignty being Brazil and Argentina, whose combined output amounts to only a small percentage of the world's production. The United States and Great Britain are to-day the world's largest consumers, with France and Italy next. The leading European position in the electrical industry formerly held by Germany has been taken by England, which now has become one of the world's largest consumers of sheet mica. It is worthy of note that during the war Germany and her allies did not have access to a single sheet-mica producing locality.

In the following discussion it has been the aim to give such available information as to the character of the world's mica deposits, their production, and their geographic locality that something may be inferred as to the future relation of production to consumption. The countries are arranged under the continents in the order of their relative importance as mica producers. The order of arrangement of the continents is geographic—in fact, the order in which the countries are described is the same as that given above in tabular form.

NORTH AMERICA.

UNITED STATES.

The sheet mica produced in the United States is all muscovite. Sheets of clear phlogopite, used for stove fronts, were mined in northern New Jersey about 40 years ago, but there has been no recent production. Small quantities of scrap biotite and of scrap phlogopite, suitable only for grinding, are produced now and then. Compact granular lepidolite and roscoelite are mined annually, not because of their micaceous properties but chiefly because of their lithium and vanadium content, respectively. Clinochlore, a micaceous mineral resembling mica in some of its physical properties, is also mined.

Sheet mica comes annually from about 10 States, but commercial sheet mica has been obtained from at least 19 States, and occurrences

of such mica are known in at least 6 more, so that altogether 25 States are known to contain sheet mica in varying quantity and of varying quality.

Mica-bearing pegmatites are generally associated with highly metamorphosed rocks of very great geologic age, such as schists and gneisses, although a few deposits occur in granite that has not been strongly metamorphosed. Most of the altered schists and gneisses containing mica-bearing pegmatites are of pre-Cambrian age. A study of a geologic map of the United States indicates the possibility of the occurrence of mica deposits in the following regions:[1] In the eastern Appalachian region from Alabama to New York State and in the New England States; in northern Wisconsin, Michigan, and Minnesota, and in the region including corners of Minnesota and Iowa and part of South Dakota; in the Black Hills of South Dakota; in the Rocky Mountain region from Texas to Montana; and in many smaller and more or less isolated areas in nearly all of the States west of the Rocky Mountains.

The States containing deposits of commercial sheet mica may be grouped geographically as follows. The States in which the deposits have not been successfully worked in recent years are indicated by an asterisk (*).

Southeastern States: North Carolina, Georgia, Virginia, South Carolina, Alabama.
Eastern States: * Maryland, * Pennsylvania, * New Jersey, * New York.
New England States: New Hampshire, * Maine, * Vermont, * Massachusetts, * Connecticut.
Western States: South Dakota, Idaho, * New Mexico, * Colorado, * Wyoming, * Texas, * Utah, *Arizona, * Nevada, * California, * Washington.

The important mica-producing States are North Carolina and New Hampshire; minor mica-producing States are Georgia, Virginia, South Carolina, Alabama, South Dakota, and Idaho. New Mexico and Texas are reported to contain mica deposits of considerable extent and value; the deposits in the remaining States are of problematic value.

The mica deposits of the United States have been described in detail in the annual reports on the production of mica, supplemented by several separate economic reports. The important papers are listed in the selected bibliography at the end of the present report.

The great demand for sheet mica of good quality for use in the manufacture of condensers naturally stimulated inquiry relative to the increased production of such mica in the United States. Because of unusual economic conditions, the contemplated increased production of mica was adversely influenced by other factors. For the country as a whole the production in 1918 was not much greater than that of previous years, Georgia being the only State to show an abnormally large increase in its production.

The southern mica field, including the western portion of North Carolina, with adjacent parts of Virginia, South Carolina, Georgia, and Alabama—a field producing about two-thirds of the domestic sheet mica—has always been handicapped because it is essentially an agricultural and not a mining region. Farmers do most of the mining, and in consequence there is at many places no continuous

[1] Sterrett, D. B., U. S. Geol. Survey Mineral Resources, 1914, pt. 2, p. 68, 1916.

development of the mines. Many of the miners work their deposits on a very scanty capital and, not being used to mining on a large scale, cease operations because of such relatively unimportant and easily remedied conditions as the presence of ground water, lack of pumps or other machinery, caving in of tunnels and shafts, a slight decline in the price of mica, or depletion of a small lens of mica with consequent necessary dead work for a period. The mining of mica is exceptionally hazardous and often a good deal of dead work has to be done, especially if the mica occurs in lenses through the pegmatite. As a result there is a tendency to be ultraconservative, especially in newly opened regions. Another thing that has large influence in retarding the extension of mica mining throughout the South is the fact that the miners do not appreciate how much the salability of mica depends on its quality and on the size of the usable mica and not on the size of the material as mined.

These statements apply more to the numerous small prospects and the newer localities of the southern mica field than to the older established mines, some of which have been worked for many years. Other factors influencing adversely the development of some of the mines are the lack of cooperation, each owner or miner working independently instead of coordinating; the practice of "gophering" and of not timbering the shafts and tunnels, which makes the reopening of old mines extremely dangerous; the lack of stability of price, especially of the smaller sizes of mica, so that mines which do not yield large sheets could be profitably worked; and the effect of the importation of mica, chiefly from India, on the prices paid for the domestic mica.

Mica mining in New Hampshire is conducted under two additional difficulties produced by the cold winters and the hard, compact pegmatite rock carrying the mica. The mining operations in New Hampshire in 1918 produced some excellent mica, but that they were not eminently profitable is shown by the fact that in 1919 these operations have almost ceased. Undoubtedly a good deal of excellent sheet mica still remains in the New Hampshire mountains; whether this can be extracted profitably is uncertain.

South Dakota and Idaho and to a less extent New Mexico and Texas gave very disappointing results in 1918 in view of their supposed ability to produce good sheet mica. The lure of selling stock instead of the actual production of the mineral adversely influenced mica mining in some of these States.

CANADA.

The mica produced in Canada is phlogopite. Practically no muscovite mica is mined here, though several deposits have been worked in a small way in the past, and potential deposits of muscovite are reported to occur in the western part of the country. Small quantities of phlogopite have been produced from Ceylon, Madagascar, South Africa, and other countries, but Canada is commercially the only source of supply of this mica. The quality varies, as in all mica deposits, but excellent phlogopite is produced as well as inferior material.

The deposits lie chiefly in two well-defined areas in the Provinces of Quebec and Ontario. In Quebec the mica deposits now developed are

immediately north of the city of Ottawa, in the county of Ottawa, bordering on and between Lievre and Gatineau rivers. The principal townships containing mica mines are Templeton, Wakefield, Hull, and Portland. The mica-bearing dikes extend westward into Pontiac County as far as the townships of Bryson and Waltham, and eastward into Montmorency and Wolfe counties, near Quebec. The northern extension is not known, but the total mica area is large. The mica deposits do not extend south of the city of Ottawa and may be said to be concentrated in the area between longitude 75° 30′ and 76° (about 30 miles) and latitude 45° 30′ and 45° 45′ (about 18 miles).

In the Province of Ontario the deposits lie in an area east of the Kingston & Pembroke Railroad, south of the Canadian Pacific Railway, and due north of the city of Kingston. The district extends from about longitude 76° 10′ to 76° 40′ and from latitude 44° 25′ to 44° 55′, and measures about 30 miles from north to south and 25 miles from east to west. It is in the counties of Frontenac, Lanark, and Leeds. In this district there are two main mica areas—that of Sydenham, in the south, in which the chief mines are in Loughborough and Bedford townships, and the Stanleyville, Micaville, or Perth area, to the north, in which the mines are chiefly in the townships of North and South Burgess and North Crosby. Deposits of phlogopite are known to occur outside of the area described. Mica has also been mined to a slight extent in Nova Scotia and in Newfoundland. From Newfoundland 12 barrels, valued at $243, was shipped in 1887, and nearly 26 tons, valued at $661, in 1899. These deposits, however, consist chiefly of scrap mica and have very little commercial value and no economic future.

Nearly all the phlogopite mined is sent to Ottawa, which lies between the two fields, for trimming, grading, and marketing, and most of it is exported thence to the United States.

The phlogopite mines of Canada are in dikes which cut limestone or gneiss and are composed essentially of a pyroxene, phlogopite, calcite, and apatite. The mica occurs either concentrated along one or both walls of the dike, in the dike itself, or in the neighboring country rock, or else it constitutes the principal mineral in concentrations or pockets in the dikes, either separated pockets or a line of such lenslike concentrations, lying in more or less well-defined shoots. At some places the calcite has been dissolved away, leaving cavities partly filled and lined chiefly with phlogopite crystals.

Many of these mica mines were originally opened for their phosphate content (apatite), and the mica was at first discarded. The utilization of the small irregular pieces of mica as splittings led to the working of many of the old mine dumps.

The geologic occurrence, character of the deposits, and methods of mining of the phlogopite mica in Canada have been so well described by De Schmid [1] that it is unnecessary to repeat the information here. As stated by him,

> The mica-bearing area is covered with small excavations, ranging from 2 to 10 feet in depth, all of which have been opened on small pockets of mica. * * * The extent of the distribution of the mica-bearing rocks

[1] De Schmid, H. S., Mica, its occurrence, exploitation, and uses: Canada Dept. Mines, Mines Branch, Rept. 118, 1912.

throughout almost the entire region comprised between the Gatineau and Lievre rivers in the Province of Quebec, and also in the Perth-Sydenham area in the Province of Ontario, is such as to well justify one in assuming the existence of as valuable unexploited bodies of the mineral in these districts as have already been disclosed in the mines.

Few deposits have been exploited to a depth of over 200 feet, but in cases where this or a greater depth has been reached, indications of a continuance of the mica in depth have usually been found favorable.

Mica of considerable value was mined and shipped from Canada in the eighties, but it was not until 1906 that accurate information regarding the quantity of mica produced became available. For the period 1906 to 1917 the average annual production of mica was 714 short tons, with a minimum of 369 short tons in 1909 and a maximum of 1,208 short tons in 1916. The production of mica in Canada does not show any great annual fluctuation. The quantities reported, as given above, represent the returns published by the Canadian Government and include all kinds of mica from the sheet to the mine-run only roughly cobbed. It is impossible to give accurately the percentage of sheet mica (including splittings) represented by the reported production. In the table of world's production of sheet mica, already given, it was estimated that half of the reported production could be represented as sheet (that is, uncut sheet and splittings), although it is freely admitted that the estimate of half is only a guess, made in the absence of any exact information. If half of the reported production was sheet mica, Canadian phlogopite, for the period 1906 to 1917, constituted 11 per cent of the world's production of sheet mica, according to the table given on page 634. The average annual production of sheet mica in Canada for this period then amounted to 357 short tons.

An estimated itemized account of the preliminary figures of production of mica from the Province of Quebec for 1918 gives the following figures:

Mica produced in Quebec, 1918.

	Quantity (pounds).	Value (cents per pound).
Rough culled [a]	301,000	8
Thumb trimmed [b]	409,000	26
Split [c]	139,000	42
Scrap	57,000	1½

[a] Known as mine-run or run-of-mine mica in the United States.
[b] Known as rough-trimmed mica in the United States.
[c] Known as splittings in the United States, also called thin-split in Canada. Only the smallest sizes, not over 1 by 3 inches, are split for the manufacture of built-up mica board.

On the assumption that the rough-culled mica will yield, when split, from 10 to 30 per cent of sheet, there would be a total yield of sheet (including splittings) amounting to between 60 and 70 per cent of the total production. This is higher than the estimated 50 per cent yield of sheet, which admittedly is only an approximation but is preferred in the absence of fuller details.

In recent years, up to 1913, the quantity produced in Ontario was greater than that produced in Quebec, although its value was generally less. For the three years 1913, 1914, and 1915 the two Prov-

inces produced almost exactly the same quantity, but beginning with 1916 Quebec has produced considerably more than Ontario, both in quantity and in value.

Of the mica exported from Canada for the period 1912 to 1916, 81 per cent went to the United States and 17 per cent to Great Britain. A comparison of the total exports with production, ostensibly giving the local consumption, is very likely to yield incorrect conclusions, as the mica exported is largely sheet and splittings and is therefore in a much more advanced stage of preparation than much of the mica counted as production. A consideration of the relative figures, however, strongly suggests that very little of the sheet mica mined in Canada is consumed in that country and that practically all of it is exported, a conclusion in agreement with other known conditions of the manfacturing industry of Canada.

Prices paid in Canada for the different sizes of sheeted or trimmed phlogopite average about as follows:

Prices per pound of phlogopite mica in Canada in 1910, 1916, and 1917.

Size (inches).	1910	1916	1917
1 by 1	$0.04	$0.06	$0.09
1 by 2	.09	.13	.14
1 by 3	.17	.18	.24
2 by 3	.43	.43	.45
2 by 4	.63	.65	.80
3 by 5	.80	.90	1.65
4 by 6	1.13	1.25	2.10
5 by 8	1.67	.....	2.50
Over 5 by 8	2.00	.....	.....

Muscovite in large and clear sheets has been reported from numerous places in the Province of Quebec, especially in the Saguenay district, on lower St. Lawrence River below Quebec, and in the counties of Ottawa and Berthier. Isolated deposits are also found in the Province of Ontario. The available information on these muscovite localities is given by De Schmid. Most of these deposits were soon abandoned, and there has been no recent production of muscovite in Canada, the more lucrative phlogopite monopolizing the mica miners.

Good muscovite mica is known to occur also near Tete Jaune, in British Columbia. The mica is clear and has a very light greenish tint and seems to be of excellent quality. Especially large clear sheets are said to have been obtained here, cut sheets measuring 18 by 11 inches being reported. Sheets of mica, as found, are said to be abundant in sizes a foot square and sheets 2 by 3 feet were encountered. The mica cleaves well and is partly clear, though some of it is considerably spotted with iron oxide. It is claimed that out of a lot of 2 tons extracted in 1914, half could be trimmed into sheets 2 by 5 inches. Tete Jaune is in the southeastern part of Cariboo County, about 35 miles west of Yellowhead Pass through the Rocky Mountains, on the Grand Trunk Pacific Railway, and about 120 miles north of Revelstoke, on the Canadian Pacific Railway. The mica-bearing pegmatites, as much as 50 feet in width, are high up on the mountains, at 5,000 to 7,000 feet above the sea, on the

south bank of Fraser River. The outcrops extend for many miles, from a point below Tete Jaune to Albreda Summit, near Canoe River. The production has been small; the total quantity sold has amounted to only a few tons, consisting of small lots taken out during the last 20 years. The entire field is still in a preliminary stage of development, but it seems to warrant careful investigation, according to several reports, and unless transportation difficulties should be too severe, it may develop into a future producing area Transportation, however, seems to be an important factor, as all supplies have to be carried for many miles by pack trains over bad trails. The country rock is said to consist of mica schists and gneisses. The winters are very severe, and all transportation has to be done during the summer.

GUATEMALA.

A mica zone is known to occur near the center of Guatemala, north of Guatemala City. The mica outcrops are in the States of Baja Verapaz and Quiche. The outcrops in Quiche are near the boundary with Baja Verapaz but apparently have not been worked on a commercial scale. In Baja Verapaz deposits at two localities have been exploited, the high price of mica having stimulated prospecting and development work. The pioneer in mica development work in Guatemala was the Guatemala Mining & Development Co., an American firm, which about 10 years ago spent considerable money in the exploitation and development of mica properties in Quiche and Baja Verapaz. This company ceased active operations after mining only a small quantity of the mineral. Sarecky & Chellis, American operators, are to-day the principal shippers of mica from Guatemala. A number of small prospectors are endeavoring to develop mica properties, but owing to the difficulty of procuring satisfactory and trustworthy labor, to the occurrence of the mica in hard rock, which has to be blasted, causing much waste and ruining the larger sheets through the development of hair cracks, and to the lack of explosives, the importation of which is prohibited, except under special permit of the Guatemalan Government, the operators have not yet been able to produce mica in large quantity. Muscovite from a deposit near Chol, Baja Verapaz, ranges in color from white to rum and has been shipped in sizes from 2 by 2 inches to 10 by 12 inches. A deposit of greenish muscovite near Salama, Baja Verapaz, has been exploited, and the product shipped.

Surface mining of mica in Guatemala, owing to the large incidental waste, costs about 25 cents a pound; the mica must be transported from the mines to the nearest railroad station (Guatemala City) by mules, which are scarce and expensive; the cost of railroad transportation to Puerto Barrios is $24 a ton; and the cost of ocean transportation from Puerto Barrios to New York is about $20 a ton.

Several shipments of the greenish mica from Guatemala were tested by the consumers of sheet mica for use in the manufacture of high-tension condensers, with general unsatisfactory results. So much of the mica as received is flawed that it takes from four to six times the quantity of Guatemala mica, as compared with other mica, to yield the same quantity of cut mica. With the Guatemala mica

bidding for about the same market price it obviously finds very little sale. Another objection to this mica lies in the fact that it does not split freely and evenly and therefore does not lend itself readily to the preparation of the very thin films of mica required in condenser work. It may be, however, that the mica would be more suitable for glazing, as in the fronts of stoves, and for general electric insulation where no high potentials are used.

MEXICO.

A dark amber-colored phlogopite mica has been obtained from a deposit near Guadalajara, Mexico. The associated rock is said to be limestone, but it is not known whether the mica occurs in limestone or in calcite veins, such as are found in Canada. Small lots have been sent to the United States, but it is not thought that the locality will produce much mica of value. Mica in sheets 6 by 6 inches was also reported in 1898 to have been found near Villa Corona, Durango, about 40 miles from the railroad.

SOUTH AMERICA.

BRAZIL.

Muscovite of excellent quality has been found in Brazil in the contiguous States of Bahia, Goyaz, Minas Geraes, and Sao Paulo. Minas Geraes contains especially valuable deposits in the neighborhood of the city of Santa Luzia de Carangola, on the Leopoldina Railway; near Pecanha; northeast of Itabira de Matto Dentro; near Bicas; at Villa Rio Piracicaba; and near Sao Domingos do Rio do Peixe, in the municipality of Conceiçao. The mica is exported from Rio de Janeiro. The most valuable deposits in the State of Goyaz are found in the municipality of Meia Ponte. In Sao Paulo deposits of mica have been discovered on Bananal, Itapecerica, Parnahyba, Sao Bernardo, and Juquie. The mines at Juquie, in the neighborhood of Itapecerica, are mostly near the Government railway between Itapecerica and Prainha, in the neighborhood of Iguape, at the point where the railway crosses Juquie River. There are large mines on the right side of Braco Grande River, 11 miles south of the village of Juquitiba. In Bahia the mica deposits are between Jacobina and Villa Nova, in the valley of Itapecuru River, and near Paulo Affonso Falls.

The producing mines are in pegmatite dikes and lenses as much as 20 feet wide, which occur in the metamorphic schists that form the country rock. The pegmatites are greatly decomposed, the feldspar being altered to kaolin to a considerable depth. The mica crystals are irregularly disseminated through this soft kaolinized feldspar. The adjacent metamorphic schists are also greatly decomposed at many places.

Much of the mica mined is excellent in quality and very similar in both quality and texture to the Indian ruby mica. The mica crystals measure as much as 20 by 10 inches across and 6 inches thick, and an average size for the crystals is about 6 by 6 inches and 3 inches thick. A considerable quantity of the mica crystals are soft and

decomposed, but others are firm and hard. The Brazilian mica, as mined, after the worthless material has been rejected, produces about 10 per cent of knife-trimmed sheet, which, if carefully trimmed, yields an average of about 50 per cent of cut sheet.

It is stated that the Brazilian mica industry should prove to be very lucrative, for properly prepared, the mica is well thought of in foreign markets. Considerable capital has been invested in the industry, and special attention has been given to the preparation, classification, and packing of the mica to meet the requirements of the foreign purchasers. Some of the difficulties in the development of this industry are lack of transportation facilities to the distributing centers and ports of departure, scarce and inefficient labor, and excessive rains and fever.

The production of sheet mica in Brazil was relatively small before the war. For the period 1902 to 1913 the total production was about 116 short tons, or an annual average of not quite 10 tons. The value of this mica was estimated at $300 to $400 a ton. In relation to the world's production, Brazil produced in the period 1902 to 1913 about one-third of 1 per cent. For 1914 Brazil's production of mica amounted to 17 short tons, of an average value of $836 a ton. Since then both the quantity produced and its value have increased considerably, 59 tons for 1916, 106 tons for 1917, and an estimated production of 125 tons for 1918. The mica in 1916 had an average value of $921 a ton and in 1917 of $1,245 a ton, or more than 50 cents a pound, a good indication of the real value of Brazilian mica when properly selected, trimmed, and sorted. For 1917 the quantity of mica produced in Brazil amounted to nearly 3 per cent of the world's production, an increase of 10 times the relative production before the war.

ARGENTINA.

The mica shipped from Argentina to the United States is muscovite. So much of this mica was spotted and stained that Argentine mica was becoming known as stained mica, but recent shipments have included good clear mica, and it is possible that further development will show that Argentina can produce a considerable quantity of that grade. One reason advanced for the former preponderance of stained mica in the material exported was that most of the clear mica was consumed locally in the electrical industries, although the quantity so used probably does not exceed 1 or 2 tons a month, and the export figures probably closely approximate the total production.

The deposits are said to be numerous and to lie especially in the Provinces of Cordoba and San Luis. These Provinces are in the west-central part of the country, about midway between Buenos Aires and Valparaiso, Chile. The Province of Cordoba is traversed by several railroads.

The La Realidad mine, about 7 miles northwest of La Toma and south of Cienaga del Intiguasi, on the eastern slopes of Cerros del Rosario, San Luis, and a group of mines near Calamuchita, Cordoba, have shipped good sheet mica. That from Calamuchita is light brown. Other localities in the mountainous parts of Cordoba are Champagui, in Sierra del Alto, Alta Gracia, and Santa Maria. In the Province of San Luis mica has also been mined at Paso del

Totoral, Victoria Morada; in the Province of San Juan on the Usno farm, north of Valle Fertil, in the Sierra de la Huerta; in the Province of Tucuman at Monteros; in the Province of Catamarca near Tinogasta; and in the Province of La Rioja near Villa Union.

Altogether about 200 mica deposits have been opened, but only about a quarter of these were worked. The producing mines are all in the Provinces of Cordoba and San Luis, although mica of commercial value has also been reported from the Provinces of San Juan, Catamarca, and Salta.

The exploitation of the mica mines is only an incidental operation and does not constitute an established industry, being carried on in a small way by numerous private individuals. The mica is sold in the crude state to local buyers, who prepare it for sale to the exporters. Skilled labor for working the mines and properly trimming and sorting the sheets of mica seems to be scarce, but this difficulty can probably be overcome, as experience is gained with the continued exploitation of the deposits. Prices advanced materially in 1918 in Argentina, owing in part to the fact that several German companies were buying and holding mica so as to prevent its export to the Allies.

The first year of record for production of mica in Argentina is 1908, when about 1 ton was produced. The output increased with succeeding years and amounted to 21 tons in 1910, but it then decreased until in 1915 it was reported that there was no production. In the years since 1915 the production has rapidly increased, amounting to 70 tons in 1917 and to an estimated production of 80 tons in 1918. The average annual production for the period 1908 to 1913 was about 10 short tons. For the period 1914 to 1916 it was only about 3 tons, but in 1917 and 1918 the production amounted to about 2 per cent of the world's production. The destination of the mica exported in 1917 was as follows: England, 71,012 pounds; United States, 52,470 pounds; Italy, 12,099 pounds; Spain, 2,809 pounds.

PERU.

Sheets of mica 9 inches square have been found on a pegmatite dike some distance north of Mollendo (port of Arequipa), Peru. Most of the mica, however, was small, not more than 4 inches square. Several hundred pounds of mica is reported to have been exported annually from Peru to the United States in the last few years.

EUROPE.

NORWAY.

The Godfjeld mine, near Skutterud, on the southwestern coast of Norway, has been developed on a pegmatite dike nearly 100 feet thick. The mica crystals are mostly small, but plates measuring 1 by 2 feet have been found. The mica is greenish, but the many stains and mineral inclusions give it a brown appearance. The books of mica are intergrown and wedge shaped, so that the cleaved pieces do not have parallel surfaces. At a depth of about 60 feet the mica was found to be soft and brittle and was described as being rotten and

altered to some much softer material. The mica occurred in shoots or lenses in the pegmatite, and excavations were carried down to 100 feet. There was no production of mica from Norway for many years before the war; but it is reported that mining was feverishly renewed toward the end of the war and that some of the mica obtained was sold to Germany for $70 a pound. It is worthy of note that this occurrence in Norway is the only deposit of sheet mica to which Germany had access after her intercourse with Africa was stopped.

AFRICA.

GERMAN EAST AFRICA.

The mica from the former German East Africa is an excellent dark-green or brown muscovite, splitting very easily into smooth, flat sheets, and unusually free from imperfections in structure and from inclusions of foreign mineral matter. Many of the mica sheets are clear and transparent in half-inch thicknesses. The mica crystals are large, some of them 3 by 3 feet in the rough state and yielding trimmed sheets measuring nearly 18 inches across. Phlogopite was found on Ssuwi River, but, although some good sheets having a golden sheen were obtained, most of the mica mined here was too much folded and cracked to be of commercial value.

The mica deposits are scattered over the eastern and southern part of the country, the most valuable group, centering in the Uluguru Mountains, being located at about 7° latitude and 38° longitude. The known deposits may be placed for convenience in six groups, as follows:

Mica localities in German East Africa.

Locality.	District.	Longitude (east).	Latitude (south).
Uluguru Mountains	Morogoro	38°	7°
Do	Mbakana River	37½°	7½°
Do	Nguru Mountains	38°	6⅓°
Usambara	Mombo	38°	5°
Do	Schuerffeld Roland	38½°	4½°
Mahenge	Tangiro	36°	9°
Lindi	Mawa	39°	11°
Do	Muera	39°	10°
Woto		34½°	9½°
Pongive Mountains	Ssuwi River	38½°	6½°

The Uluguru Mountains contain the most valuable mica deposits of German East Africa. The deposits are grouped around three distinct places: (1) those in the Morogoro district, in the north end of the Uluguru Mountains; (2) those on Mbakana River, in the southern part of the range; (3) those near Mkondami, in the Nguru Mountains, the northern extension of the Uluguru Mountains. Some of the localities in the Morogoro district, chiefly Mhindu, Nguru, Kigambue, and Mssassa, north of Morogoro, contain very many nearly vertical pegmatite dikes, 15 to 20 feet thick, cutting the country rock, which is chiefly biotite gneiss and mica schist. The dikes trend east. Large bodies of massive quartz are abundant, especially in the center of the dikes. The very abundant mica lies

between the quartz and the outer zone of granular pegmatite, feldspar being the other component mineral. The mica zone attains a width of 5 feet. The dark-brown transparent mica sheets are abundant in sizes as much as 18 inches across. The deposits on Mbakana River, a tributary of Mgeta River, are also very valuable. Excellent mica of a greenish or brownish color, in transparent sheets free from fractures and mineral inclusions, has been abundantly obtained from the numerous nearly vertical pegmatite dikes cutting the predominant biotite gneiss. The dikes have a mixiumum thickness of 70 feet and contain much massive quartz, on the edges of which is abundant mica. The mica zone attains a thickness of 15 feet. The pegmatites are not much decomposed, and bent or cracked mica sheets are rare. Crystals measuring 35 by 31 inches have yielded trimmed sheets, free from flaws, measuring 18 by 15 inches. The largest crystals found are 3 feet across and nearly 1 foot thick. Crystals measuring about a foot across are very common.

In Usambara, near the border of British East Africa, excellent mica has been found in the many pegmatites cutting the gneissic country rock. At Neu Hoeffinghoff, slightly north of Mombo, pegmative dikes, striking northwest and as much as 30 feet thick, have yielded excellent mica of a smoky brown color as well as crystals of a very light color. The pegmatites average about 5 feet in thickness, with massive quartz in the middle and feldspar and mica on the edges. Many lenslike concentrations of mica are encountered; other minerals in the pegmatite are tourmaline and garnets in large crystals. The mica plates attain a size of 4 by 1½ feet and trim into large, clear sheets. Northeast of Mombo and about 10 miles northeast of Wilhelmsthal (about halfway from Mombo to the border of British East Africa), at Schuerffeld Roland, smoky brown sheets of mica, with some magnetite inclusions, have been obtained from pegmatites. The mica sheets split easily, are very flexible, and measure several feet across. In the Mahenge district good sheet mica has been obtained at Mount Fissage and near Tangiro; other localities are at Mawa and Muera, in the Lindi hinterland, in the southeastern corner of the country; and in the Woto plateau, in the Langenberg district, in the southwestern part of the country, near the north end of Lake Nyassa.

All the localities mentioned yield only muscovite, but on the Ssuwi Stream, which flows down the northern slopes of the Pongive Mountrains, a few miles west of Bagamoyo, there is an area of strongly weathered augite rock (pyroxenite?), measuring about 600 by 360 feet, which has yielded thick plates of phlogopite mica, occurring in nests and associated with apatite, calcite, magnetite, ilmenite, and tourmaline. Graphic granite pegmatites also occur here, the country rock being a gneiss. Excavation to a depth of 12 feet yielded some good sheets of mica, although most of it is considerably folded and cracked.

Practically all the deposits, which were first opened about 1902, are small excavations of the open-quarry type. One of the drawbacks formerly existing was the very cheap license fee (2 cents per claim for the first year and 12 cents per claim for the second year) under which claims could be held on speculation without being worked. This hindrance seems to have been removed, and mining

has been actively developed, especially since about 1908, after which more than 100 tons of choice trimmed mica was produced annually. Transportation seems to have been one of the main difficulties, as the country around the mica mines has been only partly opened. The deposits, however, are not for from the seacoast and lie almost directly west of Dar-es-Salam, and with an assurance of steady production the transportation problem would be readily settled. It is stated that the mines have been worked by the British military authorities and that before their seizure they were yielding mica at the rate of nearly 1,000 tons a year. A concession of exclusive rights to exploit mica deposits in Concelho de Lago was recently granted by the Government of Portuguese East Africa, but it is not known whether the deposits lie in that country or the adjoining German East Africa.

The output of German East Africa in relation to the world's production in 1906, the first year for which a comparison can be made, amounted to about three-fourths of 1 per cent. For the period 1907 to 1913, it amounted to 3.4 per cent, and for 1913, the last year for which authentic figures are available, it amounted to 4.3 per cent, showing a steady increase. From informal reports it seems as if the production during the war had increased very much. From 1902 to 1907 the average annual production was 21 short tons; from 1908 to 1913 the average was 127 short tons.

After India, the United States, and Canada, German East Africa is the largest producer of sheet mica and holds forth the most promising future. It would thus rank third in actual value of output of muscovite mica in the world.

UNION OF SOUTH AFRICA.

The important mica deposits, all muscovite, in the Union of South Africa are in the Transvaal. Other Provinces of the Union known to contain commercial sheet mica are Natal and Cape of Good Hope (Cape Colony). The Transvaal deposits are in the Leydsdorp division of the Pietersburg district, a well-defined mica belt 50 miles long and from 2 to 4 miles wide extending along Olifant River, southeast of Leydsdorp, from a point near Mica siding, on the Leydsdorp Railway, eastward toward Portuguese East Africa. Operations have been limited to three areas—(1) near Mica siding, 22 miles east-southeast of Leydsdorp; (2) about 25 miles east of Mica siding (Union mica mines); and (3) 75 miles east of Leydsdorp, near the junction of Malelane and Olifant rivers (the Malelane mica fields).

The muscovite from the Transvaal, the only Province yielding a fairly constant production, is mostly of a pale-brown color, but that from the Malelane field has a pale-green tint. The mica books or crystals are usually very large, the largest being 5 feet across and 1 foot thick. Much of the mica is spotted and defective, although clear brown mica, cleaving freely, is found in the large crystals. Many of the books are spoiled by the presence of vertical cracks or inclined gliding planes which pass right through them. Other crystals are buckled and present a wavy surface, and in still others the cleavage plates are of uneven thickness.

The mica varies considerably in quality. A small proportion of the mica books contain beautifully clear brownish muscovite, free from flaws and of excellent splitting quality, but many of them have a spotted or mottled appearance, owing to the presence between the laminae of numerous inclusions of deep-brown or blackish-brown color. These inclusions are frequently arranged in lines cutting one another at angles of 60°. The nature of these inclusions has not been determined, but careful tests have shown that their presence does not materially impair the electrical resistance of the mica. The green mica occurring at Malelane has a greasy feel, is somewhat soft, and seems to be of exceptional quality.

The clear brownish muscovite of the Leydsdorp fields has been proved to be equal to the best grades of Indian and Canadian mica in dielectric strength. It is slightly harder than Canadian phlogopite and certain varieties of Indian muscovite and therefore not quite so well adapted to armature work. The greenish mica from Malelane appears to be softer, and it is very desirable that its suitability for this purpose be practically tested.

The mica occurs in conspicuous dikes of coarse white pegmatite, with a prevalent easterly trend, following the southern margin of a great elongated batholith of newer granite—the so-called Palabora granite—intrusive in the older granite, gneiss, and schists of the Swaziland system. The dikes, which are very numerous, are several hundred yards in maximum length and 40 feet or more across. They present the usual characteristics of pegmatite, being subject to abrupt variations in width and taking unexpected twists and turns. The pegmatite is composed essentially of quartz, albite, and mica, which in some localities, notably at Malelane, are accompanied by fluorapatite, garnet, and tourmaline. Here, as in other parts of the world, the distribution of the larger plates and crystals of mica through the pegmatite is very sparse and sporadic, the best books being generally aggregated in irregular pockets or in vertical or highly inclined leads resembling the ore shoots of mineral veins. Some pegmatite dikes are much richer than others, but the average proportion of merchantable mica is probably not more than a few hundredths of 1 per cent of the total dike rock.

Most of the workings are small open cuts, the deposits nowhere having been followed down for more than 50 feet.

Between 1910 and 1912 hundreds of mica claims were taken up by prospectors, syndicates, and companies in the Transvaal, but the lack of a convenient market soon caused most of the miners to quit operations. After a few years practically all the claims were allowed to lapse, and in 1916 the last company ceased operations. In 1917 and 1918, however, operations were resumed by a few of the larger companies, and several tons of sheet mica were produced, four white men and 150 natives being employed. Splitting, grading, and cutting sheds were erected, and it is said that the equipment included 45 improved cutting machines. South African consumption of mica is very small, only some of the larger sheets of best quality being consumed by the electrical and power companies on the Rand and elsewhere. A small mica factory was established at Johannesburg, which manufactured mica lamp chimneys, stove fronts, and built-up mica board to a moderate extent. The mica-mining industry is

dependent on its export trade and requires great care in grading and packing the mica.

In the Cape Province muscovite has been found in pegmatite veins in granite at Alicedale and Middel Water in Prieska. Only rarely can sheets be obtained exceeding a few inches in size, and almost invariably they are bent or crumpled. The granites have been considerably affected by earth movements subsequent to the formation of the pegmatite veins, and the mica crystals have in consequence been distorted. Mica has also been mined at Jackalswater, north-northeast of Steinbock, in Little Namaqualand, and it was understood a cutting machine was at work in that district. Plates as much as 14 inches across have been found, but they were badly flawed and of little commercial value. At one place greenish mica sheets measuring 5 by 7 inches were abundant. Rich mica dikes are reported on the Bloemsemond farm, in the Gordonia district, but no further information is available.

In Natal mica has been worked in the Umfuli Valley, near Melmoth, and on Mvuzana River, at Fort Yolland, near Eshoe. The last work on the deposit at Fort Yolland was done in 1914. The mica occurs in pegmatite cutting hornblende schist. The pegmatite, veins are very irregular and disconnected and range in width from a few inches to 8 feet. The mica is found in "books" from 2 to 6 inches in diameter and 1 to 3 inches in thickness, sparsely scattered through the pegmatite. A very large amount of waste material must be removed in order to extract the mica, which, although of good color, is frequently cracked and bent, owing to the movements to which the pegmatites have been subjected.

The following is a record of prices paid for Transvaal mica, sheeted and packed in wooden cases, in 1917:

Prices of Transvaal mica in 1917.

Size (inches).	In Africa.	In London.
2 by 2	$0.91	$0.97
2 by 3	1.22	1.34
2 by 4	1.62	....
3 by 3	....	1.82
2 by 6	2.43	....
3 by 4	2.68	2.68
4 by 4	....	3.28
3 by 6	3.28	3.41
6 by 6	....	4.38
8 by 8	....	4.87

The total production of the Union of South Africa, as reported, including the two-year period (1902 and 1903) when mica was shipped from Natal, amounts to about 123 short tons, valued at $58,912. The first production in 1902 was that from Natal. Production in the Transvaal began in 1909, and has continued more or less regularly, with an average annual output from 1909 to 1917, of about four tons. The relative importance of the Transvaal mica field would thus seem to be slight. The period of nearly 10 years of experience in developing the mica field should show a much larger production if the field is important. The reason of the cessation of

production from Natal is not known, but from general considerations it seems unlikely that any part of the Union will develop into a large mica producer.

MADAGASCAR.

Information about commercial mica in the island of Madagascar is very difficult to obtain. Sheet muscovite is reported from many of the pegmatites of the high plateau in the center of the island. Brown muscovite (probably rum colored) is said to be abundant at Ambatondrazaka and Ankazobe. A valuable deposit is reported to occur in the pegmatites of the Olotsingy Mountains, south of Betafo and Ambatofotsikely. It is stated that about 10 tons a month could be produced from these localities. A white muscovite is reported from the Nossi district and from a locality near Varika, in the Province of Mananjary. About 15 per cent of the mica mined in Madagascar is clear, the remainder being very much spotted and stained.

Phlogopite mica is abundant in some of the metamorphosed limestones, especially in those containing humites. Large sheets have been obtained near Ampikaza, Tananarive, Mahafaly, and Fort Dauphin.

Only a very small production of mica is reported from Madagascar. The largest annual output was 6 tons, valued at $442, in 1913, the latest year for which figures are available. The total reported production before 1913, beginning with 1908, amounted to only 1 or 2 tons.

NYASSALAND PROTECTORATE.

Considerable mica was produced in the Nyassaland Protectorate in 1910 to 1912, the total yield being 119 short tons, valued at $55,693, an average of $468 a ton. Such a value would indicate that the mica was of high quality, but no information is available as to the exact location or character of the deposits. It is to be noted that the region lies west and southwest of German East Africa.

RHODESIA.

Dikes of coarse-grained pegmatite containing large books and crystals of muscovite are of fairly common occurrence in the basement complex of southern Rhodesia, but as yet no mica has been mined in that territory. Specimens of clear transparent mica, as much as 5 inches across, were found to be thoroughly satisfactory for electrical insulation. No particulars are known regarding the nature or situation of the deposit. Sheet muscovite has been reported from Limpopo River, in the Tuli district, and from the vicinity of Urungive, in Mashonaland. The occurrence of lilac and blue lepidolite and bronzy zinnwaldite in large crystals, as much as 6 inches across, in lithia greisen southwest of Odzi siding, in the Umtali district, has recently been reported. Lepidolite, the lithium mica, is also found in scaly granular forms without crystalline outline and in compact aggregates in greisenized pegmatite in the Victoria, Belingwe, and Salisbury districts.

PROTECTORATE OF SOUTHWEST AFRICA.

Mica-bearing pegmatites have a wide distribution in the central and southern portions of southwest Africa. Several dikes of muscovite pegmatite southeast of Klein Kharas, in the Keetmanshoop district were opened some years ago, but most of the mica, which was 8 inches or less in diameter, proved, on being tested electrically, to be too badly flawed to be of commercial value.

KAMERUN.

A good quality of muscovite mica in sheets measuring 16 by 24 inches has been found in pegmatites in Kamerun at Woe Matun, in Dualabezirk, and at Essudasa, in Ossidingebezirk. The difficulties of transportation, however, are so great that they prohibit exploitation. No further information about the character of the deposits is available.

ASIA.

INDIA.

The mica exported from India is all muscovite. A little biotite, obtained in mining the muscovite, is consumed locally, as a medicine, and insignificant quantites of phlogopite have in the past been extracted in Travancore, in southern India, and exported. Negotiations were opened in 1918 looking to a further development of the Travancore properties. The Indian muscovite, like that in all other deposits, ranges in quality from the best to the poorest, but more first-class mica is mined and shipped from India than from any other country. The best mica in Bengal when in plates half an inch thick, has in transmitted light a deep ruby color; hence the term "ruby mica." It has been estimated that only about 5 per cent of all mica received in England from India was suitable for use as electrical condenser mica. Indian mica has been classified as clear ruby, smoky, brown, pale amber, green, slightly stained, black spotted, and silver-white soft. An even more detailed classification has been made by the British Government as a basis for price fixing and is given on page 656. India has been, is to-day, and will continue to be the preeminent mica-producing country of the world. The best Indian mica is unexcelled, and the many years of experience in trimming, sorting, and packing makes shipments of the Indian mica the most desirable.

Commercial mica deposits in India are limited to the peninsula, south of the deformed crystalline rocks of the Himalaya Mountains. The principal mica-producing areas are in Bengal and Madras, but several other parts of India have produced good sheet mica, chiefly Rajputana and Mysore. For the period 1910–1917 Bengal produced about 75 per cent of the sheet mica, Madras about 22 per cent, Rajputana nearly 2 per cent, and all the other localities less than 1 per cent. In these years Bengal has increased its proportionate production, while Madras and Rajputana have relatively decreased.

The mica-producing region in Bengal (which is also described as being in Bihar and Orissa) is in a belt of schists and associated gneissoid granites, 60 miles long and 12 miles broad, from Bendi in the Hazaribagh district, northeastward nearly to Nawadih (Jha-Jha), on the railroad in Monghyr, south of the Ganges River and

about 200 miles northwest of Calcutta. The mica districts are Hazaribagh, Gaya, and Monghyr, but most of the mines are in the Koderma area, Hazaribagh district. The mica region extends from latitude 24° 25′ to 25° and from longitude 85° to 86° 30′.

The Koderma area (latitude 24° 31′ and longitude 85° 38′) has irregular surface features, the schist forming a scarp, which is cut by many passes and is rapidly being eroded by the action of rivers. Although most of the mica-bearing pegmatites in this area have been prospected or mined, much of the work done was superficial, and with a very few exceptions the mines are very shallow, and their excavations which strictly follow the leads of good mica crystals, are long, meandering holes reaching down to several hundred feet. Open cuts are frequently made down to about 30 feet, after which the sides begin to cave in. In many places pegmatites are decomposed to a depth of 100 feet owing to the kaolinization of the feldspar. A few mines have recently adopted [1] better mining methods with good results, and it seems probable that the extension of modern methods will be of great benefit to the Indian mica-mining industry.

The schist formation consists of mica schists, composed of quartz and mica together with one or more of the minerals kyanite, sillimanite, magnetite, chiastolite, hornblende, garnet, and scapolite, as well as quartzites and limestones. There are also schists and gneisses with diopside, anthophyllite, talc, and chlorite. The so-called dome gneiss consists of low rounded hills of a gneissic granite. Both the dome gneiss and the schists contain pegmatites, but only those in the schists carry commercial mica. The pegmatites are generally parallel to the strike of the schist but also cut across it. They range in thickness from a few inches to 150 feet, but the workable dikes average about 10 to 40 feet and are present in great abundance. The mica crystals are collected in bunches or rows along one or both sides of the dike but chiefly in shoots near the center of the dikes. At some places the mica books are best on the hanging wall, at others they are best on the footwall, and at still others they are uniformly distributed through the rock. It has been said that if masses of fairly pure feldspar contain large crystals of mica, then extensive bodies of massive quartz are present in the dike within at least 20 feet. Up to about 1900 there were from 200 to 300 so-called mines in the Koderma area, but only one vertical shaft without crosscuts or adits was being sunk. Mining conditions there have improved in the last decade or two. Very much of the mica is ruined in mining. Preliminary shafts are often sunk in the mica-bearing pegmatite instead of in the adjacent country rock, as they should be, for the mica could then be extracted from the pegmatite by overhead stoping.

One mine in a pegmatite dike 40 feet thick, worked by modern methods in 1900 for more than 300 feet, yielded 40 pounds of mine-run mica or 10 pounds of trimmed mica for each ton of pegmatite rock removed.

The other important mica area in India is in Madras, especially in the Nellore district, which extends from about longitude 79° 45′ to 80° and from latitude 14° to 15°, covering about 35 miles from east

[1] Dickson, A. A. C., The mica miner's and prospector's guide, 50 pp., 12 illus., London, E. & F. N. Spon (Spon & Chamberlain, 120 Liberty Street, New York), 1919.

to west and about 100 miles from north to south. The country rock is a mica schist with included pegmatites, forming a low-lying plain on which the rivers continually deposit alluvium. Much of the rock and many of the mica-bearing pegmatites are therefore covered and concealed and probably never will be detected. The area most intensely worked is about 20 miles wide (from east to west) and at least 60 miles long and contains many mica-rich pegmatites which are generally exploited by open cuts, mining in these flat areas being much more expensive than in the hilly ground of Bengal. The pegmatites apparently are more lenslike than those in Bengal, one of the best mines in the region being in a pegmatite body 150 feet wide and 300 feet long. Much of the mica from Nellore is of a greenish color, although brown, amber, and ruby mica is also found. A soft bleached mica with silvery luster also occurs here. A second but relatively not very important locality in Madras is at Nilgiris, in southeastern Wainad (about longitude 76° 45′ and latitude 11° 25′), where pegmatite dikes as much as 8 feet thick intrude a biotite gneiss, the mica in the pegmatites lying between the quartz and the feldspar. Much of the mica from Madras is trimmed into neatly cut rectangles of the largest possible size although some of it is sickle-trimmed, like that of Bengal. The rectangular trimmed Madras mica, however, is not "cut mica," the rectangular pieces being neither strictly rectangular nor of uniform size nor cut to any standard size.

Good sheet mica is reported to be abundant in Ajmere and in Merwara, in Rajputana, but very little is known in regard to the character of the deposits.

The mining of mica in India is very old, the mines in Bengal having been worked for hundreds of years. Those near Nellore, in Madras, are comparatively recent, having been first worked in 1887. Nearly a hundred years ago about 5,000 natives were employed in the Bengal mica mines, and it has been estimated that in the last few decades about 15,000 men, women, and children have been annually employed in mica mining.

The output in 1849, all of which was consumed locally, has been estimated at nearly 4,000 tons. The first exports of mica (410 tons) were made in 1863, the mica previously mined being used locally, chiefly for ornamentation, for medicinal purposes, and as protection against the intense heat. Probably most of the mica first exported was used in the stove industry and for general glazing. The use of mica for electric insulation and the very rapid extension of the electrical industry soon created a steady demand for mica and placed mica mining on a firm basis.

Early figures of production are probably not available. In 1890 the output was placed at 346 short tons; for the next four years the output overaged annually 206 tons; for the following five-year period, from 1895 to 1899, the average annual output was 520 short tons. In 1898 the waste heaps were turned over and considerable mica suitable for splittings was collected and split into thin films or splittings. This augmented considerably the production for the ensuing years. In 1900 the production was 1,026 short tons. Since then it has been more than 1,000 tons a year. For the 10-year period 1901–1910, the average annual production was 1,671 short tons, with a maximum of 2,677 short tons in 1908 and a minimum of 1,108 short

tons in 1904; for the seven-year period 1911–1917 the average annual production was 2,040 short tons, and for 1918 a production of about 3,000 short tons was expected. The yearly average production for the period 1901–1917, inclusive, was 1,823 short tons.

For the period 1906 to 1917, inclusive, India furnished 66 per cent of the world's sheet mica, which amounted to 73 per cent of the world's sheet muscovite, the United States, India's only serious present competitor in muscovite, producing 23 per cent.

The future of mica mining in India looks as promising as its past. Mining has not been so intensive that every deposit has been worked or that the deposits worked have been exhausted. In fact, with improved mining methods, nearly all the mines once worked, can probably be made to yield good mica again. The best of the deposits have been more or less worked, but extensive underground mining at a minimum cost would no doubt yield good returns. Additional localities in India which yield good sheet mica are being found and opened, and with a good market and fair price, the mica-mining industry should continue to flourish.

The condition of the mica trade in India was fairly good during the first half of 1914, prices being slightly lower than in 1913, which was an exceptionally good year. The trade suffered severely after the beginning of the European war, and the output decreased. A large part of the demand for this mineral had hitherto come from Germany for use in its electrical industries. Certain firms with German interests, which were large purchasers of mica, have, it is stated, closed down. The export of mica to other countries in Europe was practically cut off, and the industry generally was much hampered by the abnormally high rates for ocean freights and insurance brought about by the war. There was considerable difficulty with regard to shipments to America, to which large consignments are sent direct in normal times. A great demand for mica for use in the manufacture of munitions soon arose, however, and India was called upon for a largely increased output and made every effort to meet the requirements of the British Ministry of Munitions. Exports of mica from British India, elsewhere than to the United Kingdom, were prohibited in September, 1915. This measure was not, however, sufficient in itself to stimulate production and shipments or to insure the careful selection and grading of Government standard mica. In May, 1916, a Government agency was organized for the purchase at fixed rates of all mica suitable for munitions. Finally in March, 1917, it was found desirable to improve the system still further. Prices had meanwhile risen in the London market, and free export to that market was again permitted without the intervention of the Government agent, whose activities were then confined to the requisitioning of stocks unreasonably withheld up country. Protracted rains accounted for a temporary serious falling off in the output, but shipments steadily increased, and the production for both 1916 and 1917 exceeded that of any year since 1908. The expected production for 1918 was estimated at more than 3,000 short tons.

Attention has also been paid by the geologists of India to the geologic side of the industry, and members of the India Geological Survey have been engaged in giving technical advice and assistance in established mining areas and also in searching for new sources of

supply, especially in the Bengal region. A large number of promising veins of pegmatite containing ruby mica of unusually high average quality were found in the pegmatites of the schist area in the neighborhood of Nansa, a few miles north of Gangapur, Udaipur, and negotiations were begun for the opening of the deposits.

Mica mining is so old and well-established an industry in India that the uncertainties and difficulties incidental to such mining have been largely overcome. Labor is plentiful, transportation offers no serious difficulties, and the processes of grading, preparing, and packing the mica for shipment are better understood in India than in any other country.

A certain small percentage of the mica mined is consumed locally. Considerable mica of poor grade is used for ornamentation and decoration, and a small quantity of the larger sheets of good quality serve as the material on which pictures are painted. Although no actual figures of such consumption are available, it has been estimated that India annually consumes several hundred tons of mica, presumably chiefly sheet mica. The refuse from trimming the sheets and scrap mica otherwise obtained is also used as insulation for boiler and pipe coverings and for covering roofs as a protection from heat, a half-inch layer being said to be very efficacious.

Of the mica exported from India in 1903 to 1914 about 55 per cent went direct to the United Kingdom, 17 per cent to the United States, 16 per cent to Germany, and 8 per cent to Holland. Of the 55 per cent sent to England, a good deal was no doubt reexported to the United States and to Germany, and likewise a good deal of the mica exported to Holland doubtless eventually went to Germany. Although no figures are available, it seems probable that from 40 to 50 per cent, or nearly half, of the mica exported from India eventually went to Germany for ultimate consumption.

The relations of the figures of production and of export for India are difficult to interpret fully. The export figures represent the actual quantity of mica leaving India for any specific year and therefore represent closely the mica that actually goes into consumption, but they do not include the mica consumed in India and may represent in part mica that was mined and sold (and therefore "produced") several years before it was exported. On the other hand, the figures of production are certainly low, as much mica obtained is not reported to the Government and does not enter into the official figures of production. A table showing production and exports as reported by the Indian Government and by the British Government shows so many discrepancies that it is hopeless to obtain figures that are incontrovertible.

CEYLON.

The mica mined and exported from Ceylon is essentially phlogopite, which occurs in irregular veins, rarely more than 2 feet wide, traversing a granitic rock (granulite), especially near its contact with crystalline limestone. Detailed accounts of the occurrence and extent of these mica deposits could not be found, but Ceylon has been producing small quantities since 1897 and possibly earlier. The

production has never been large, reaching a reported maximum of 23 shorts tons in 1907. For the period 1897 to 1908 the annual average (including three years of no production) was about 5 tons. No production was reported for the period 1909 to 1912, and almost no information is available for later years. A very little phlogopite was mined in 1918.

CHOSEN (KOREA).

The mica mines of Chosen (Korea) have been described by Shigetaro Kawasaki.[1] Both muscovite and phlogopite occur and have been known and used by the natives of Chosen for a long time. In 1909 mining for mica in Chosen was undertaken by the Japanese. No figures of production or value are given in the English text of Kawasaki's paper.

CHINA.

Mica that seems to be of good quality is reported by Consul E. C. Baker, of Chungking, China, to be found near Sungpan, in the northern part of Szechwan Province, central China, and one of the large Chinese firms there, which has a branch office in Shanghai, is prepared to export this product. About 1914 the price for delivery at Shanghai was between 9 and 10 cents United States currency a pound. About 15,000 pounds can be delivered every year, but according to reports the mica has no value as sheet. Mica of good quality, somewhat cloudy but of large size, is also reported from Tschoutschong, Province of Shantung. The supply is said to be large, but the deposit is far from transportation. Large deposits are said to be exposed in an area of 50 square miles about 50 miles from Kiaochow Bay. The mica-bearing pegmatite dikes are 10 feet thick.

The samples of mica received in this country from China are worthless as sheet, and China still has to demonstrate that it can produce sheet mica of value.

JAPAN.

Persistent reports have been made of a production of mica in Japan, although no authentic information could be obtained. Several Japanese geologists have stated that no sheet mica is produced in Japan and that the imports from Japan, as stated in some reports, may have originated in some other country.

The growth of the electrical industry in Japan has been very great in the last 10 or 15 years. Japan has nearly 700 central-station systems, 530 electric power and light systems, 42 electric tramways, and 48 combined railway and lighting systems, together with 1,609 private and 53 Government plants. The country has changed from an exclusive importer of electrical goods to an exporter.

SIBERIA.

There is no authentic record of any exploitation of mica anywhere in Russia. The term muscovite or muscovy glass, derived from the old name of the Russian Empire, would suggest Russia as the source of muscovite, but the mica referred to doubtless originally came from India. Sheets of muscovite are found in many of the pegmatites of the Ural Mountains but not in commercial sizes or quantities. In recent years sheet mica has been reported as occurring at several places in Siberia. The Tasseifsk mica deposit, in Yeniseisk Province, lies on the right side of River Tasseif, near the small village called Kondakoff, about 12 miles from the point where the Tasseif falls into Angara River. Transparent sheets 2 feet across have been found here. The Kansky mica deposit, in the Krassnoyarsk district, is near the Yakovlieff ironstone mine on Kan River, near the mouth of Varga River. Mica has also been discovered at several places on the Baikal Circle Railway.

AUSTRALASIA.

AUSTRALIA.

Commercial sheet mica occurs[1] abundantly in Australia, very coarse pegmatites, usually micaceous, being of common occurrence throughout the very large areas of pre-Cambrian rocks. Sheet mica has been mined in Northern Territory, Western Australia, and South Australia and is known to be present in Queensland and New South Wales. The chief commercial mica in Western Australia is lepidolite, although sheet muscovite is also present. Muscovite is the only mica mined at the other places.

Apparently the most valuable deposit of sheet mica is in the central part of the island, at the south end of Northern Territory, in the Macdonnell Ranges. The nearest inhabited place is Alice Springs, a small mining community. This place is fully 400 miles from Oodnadatta, at the north end of the Northern Railroad line of South Australia. Oodnadatta is nearly 700 miles from Adelaide and 400 miles from Port Augusta. The nearest railway is a single narrow-gage track and until the railway line is extended entirely across the continent from south to north the deposits in the Macdonnell Ranges are too far from transportation to be worked economically. The muscovite found here occurs in abundance in large sheets, clear, light colored, and nearly free from flaws. Sheets several feet across have been obtained.

The exact locality of the mica deposit is given as the northern slopes of Harts Range in the northeastern portion of the Macdonnell Ranges, about 25 miles in an air line north-northwest of Claraville and about 5 miles southeast of the intersection of longitude 135° and latitude 23°. The deposits exploited in the past lie east and west of Mount Palmer. The country rocks are gneisses and schists, prob-

[1] The writer is indebted to Prof. W. G. Woolnough for an extended statement on the occurrence of commercial mica in Australia.

ably of Archean age, with many pegmatite dikes. These dikes are irregular in shape and size, branching out and abruptly widening and thinning. Massive quartz in large pieces is abundant, but the mica is reported to occur in an irregular and uncertain way. It is probable, however, that the small open cuts made did not suffice to indicate clearly the mode of occurrence of the commercial sheets. A number of claims were worked here in the nineties, and the following brief sketch of these claims is taken in substance from Brown's report[1] on the region.

The Oolgarinna or Chambers mine is an open cut or quarry, 15 feet deep. The country rock is a micaceous schist, and the pegmatite contains large and solid masses of feldspar and of quartz, with smaller crystals of mica. Large sheets of mica were found at the junction of the quartz and feldspar, at the edges of the dike, and around inclusions of country rock (horses) in the dike. The large mica crystals were generally on the hanging wall. Sheets 1 foot across were plentiful, and considerable mica was still seen when operations ceased. One immense crystal of mica measured 6 by 5 by 4 feet and yielded nearly 800 pounds of cut mica.

Pope's claim is a small excavation on a pegmatite carrying large masses of quartz. Valuable mica crystals lie between the feldspar and the quartz. Nearly half a ton of cut mica was obtained from this claim.

The Disputed claim was opened for 50 feet along the hanging wall of a pegmatite, striking No. 80° W. and dipping southwest. The width of the pegmatite dike is said to be about 300 feet.

Mullen's claim is on a coarse pegmatite 20 feet wide, striking N. 10° W. About 2 tons of rough trimmed mica was obtained.

Gall's claim is on a pegmatite 60 feet wide, and yielded a ton of rough trimmed mica. Other claims were known as Williams's, Stone's, Thompson's, and Floyd's. On Stone's claim, a few miles west of Oolgarinna claim, a 25-foot shaft was sunk.

The pegmatite dikes carrying mica are known to extend eastward along Harts Range for a considerable distance. The small open cuts and quarries developed did not suffice to give any indication of the abundance of sheet mica in the pegmatites, which are numerous and extend over a large area. The systematic development of this field can probably be successfully carried out by experienced miners if supported by sufficient capital and if the transportation facilities are such that the product can be brought to the market.

Prof. Woolnough regards the Harts Range deposit as one of the important mica deposits of the world, having great future possibilities.

A total production of nearly 100 tons was made in the years 1890 to 1900, and the mica as sold was valued at about $500 a ton, a very high price, especially for that time. No mining in this region has been reported since 1900.

Around Bynol Harbor, southwest of Port Darwin, in Northern Territory, an apparent extension of the Coolgardie and Pilbara

[1] Brown, H. Y. L., Reports on Arltunga gold field and Harts Range mica field, pp. 4–5, map, Adelaide, South Australia, 1897.

regions (described in the next paragraph) contains lithium-bearing pegmatites with sheets of muscovite.

In Western Australia mica-bearing pegmatites are very abundant. In the Darling Ranges, a few miles east of Perth, sheets of muscovite of fine quality 6 or 8 inches in diameter were obtained near Toodyay (formerly called Newcastle). Sheets of muscovite 3 inches in diameter have been collected near Donnybrook, about 100 miles south of Perth. At Ravensthorpe, about 130 miles east of Albany, the numerous pegmatites contain abundant lithium minerals, and large sheets of lepidolite as well as muscovite are present. Farther north, in the Coolgardie-Londonderry area, clear sheets of lepidolite 1 foot across are bundant. The maximum size is about 15 by 12 inches, and the average size 5 to 6 inches. The mica is clear and splits easily, but the low fusibility of the lepidolite detracts considerably from its value. In the Pilbara gold field, in the extreme northwestern part of Western Australia, sheets of both lepidolite and muscovite have been mined.

In South Australia the highly metamorphosed schists and gneisses of the Barossa Ranges contain many mica-bearing pegmatites. The most noteworthy locality is near Williamstown, east of Gaoler, and about 40 miles north of Adelaide. Here a pegmatite dike 10 feet wide and dipping 60° NE. has been exploited for several hundred feet. Two shafts have been sunk to depths of 65 and 36 feet. The coarsest mica is on the hanging wall and in areas a few feet across. The mica is considerably fractured and wavy and shows numerous stains and spots with occasional clear patches. The largest sheets measured 10 by 8 inches, and the average was 5 by 3 inches. In 1890 some exploiting was done on a pegmatite 30 feet wide, and books of mica 6 to 15 inches square were obtained. No figures of production before 1908 are available, and it was only in 1917 that 38 tons of mica was produced here. The average price obtained, about $44 a ton, indicates that the mica is probably not of high quality, and as the miner has to ship his product to England and await sale there, the development of this field does not look promising.

Queensland has a mica belt several miles long on Rifle Creek, a tributary of Upper (West) Leichhardt River, about 68 miles due west of Cloncurry, but the distance of nearly 500 miles to the nearest railroad militates against the development of the field. The country rock consists of hornblende and mica schists, with numerous mica-bearing pegmatites 10 to 12 feet thick. Some dikes contain very much mica, others have considerable quartz. The mica sheets reach a size of 9 inches square. Sheet mica also occurs in the pegmatites of the mining fields of northern Queensland. Pegmatite dikes containing large crystals of mica have been noted on Einasleigh River, southeast of Georgetown, and at Brookland, near Junction Creek, both within the Etheridge gold field.

In New South Wales mica-bearing pegmatites are prominent in the area northeast of Broken Hill, where sheets of muscovite several inches in diameter are obtained.

NEW ZEALAND.

Near Charleston, south of Westport, New Zealand, a large pegmatite was worked for mica in 1911 and 1912. The mica is dark colored and cross-grained, and the largest sheets obtained measured only 6 by 4 inches. Practically all the mica mined was suitable only for grinding, very little usable sheet being obtained. Large sheets of muscovite are reported to occur near Dusby Sound, in southwestern Otago.

COAL—PART A, PRODUCTION.

By C. E. LESHER.

INTRODUCTION.

GENERAL STATEMENT.

The report on coal for 1918, like the reports for 1915 and 1917, treats of production in Part A and distribution and consumption in Part B. Throughout 1918 the statistical force of the Geological Survey engaged in the collection of statistics on coal was merged with the much larger force of the Fuel Administration in the common purpose of gathering all the facts needed by the Fuel Administration and its staff in the administration of the problems of the production and distribution of fuel during the war.

A vast fund of statistical information on coal was collected through the efforts of the Fuel Administration, and the more important parts of it have been assembled for publication by the Fuel Administration in the report of the distribution division, which appears in three parts—Part I, a description of the work of the distribution division; Part II, a description of the zone system; and Part III, statistical tables. The information contained in Part A of this report is almost entirely that regularly compiled by the Geological Survey, but the data in Part B are drawn from the statistics collected by the Fuel Administration, summarized by States and coal fields and for calendar years. Because of lack of funds there is no present prospect that statistics of distribution can be compiled by the Geological Survey for 1919.

ACKNOWLEDGMENTS.

So general and hearty was the response of coal producers and shippers, railroad officials, and consumers to the many requests made of them for information that individual mention is not possible. Appreciation is expressed of the loyal support rendered by the secretaries of the local coal operators' associations, who through their intelligent and persevering efforts in the collection and interpretation of information lightened the work of the writer and his assistants. The State geologists of Alabama, Illinois, Iowa, Georgia, Maryland, North Carolina, Oregon, Pennsylvania, Virginia, and Washington cooperated in the collection of reports from the coal operators. Special credit is due to Miss Lida Mann and Miss J. M. Corse, of the United States Geological Survey, under whose direction the statistics of production of bituminous coal were compiled, and to other members of the staff in both the Geological Survey and the Fuel Administration. The statistics of anthracite were compiled by Mrs. H. L. Bennit; much of the responsibility for the statistics for 1918 contained in Part B was assumed by the writer's assistant, Mr. W. P. Ellis, of the Fuel Administration.

UNIT OF MEASUREMENT.

The standard unit of measurement adopted for this report is the net ton of 2,000 pounds, although for certain uses the gross ton of 2,240 pounds is employed. Pennsylvania anthracite is mined and sold by the gross ton, and that unit is used in the part of the report dealing with anthracite. All other statistics of production reported to the Geological Survey in gross tons have been reduced to net tons, and unless otherwise expressly stated the net ton is meant where any statement of quantity is made in the text.

There is a steadily growing sentiment in favor of the universal use of the net ton of 2,000 pounds as the standard of the coal trade, particularly for bituminous coal in the Eastern States, where now both gross and net tons are used. The use of two units is of course undesirable; but State and municipal laws in many places require the gross ton, and freight rates throughout a section of the Eastern States are now fixed on this basis, and these facts make it difficult to effect any immediate change in standard. Foreign trade and shipping rates are expressed in either gross or metric tons, and here, too, the use of two units is undesirable. The general use of the net ton in the United States, even in the anthracite region, is advocated.

REVIEW OF THE COAL INDUSTRY IN 1918.

The dominating factor in the coal industry in 1918 was the control over every feature, from production to consumption, exercised by the Fuel Administration. The chaotic conditions that marked the closing months of 1917 continued through the first two months of 1918, for the situation was so bad that no hope was entertained of getting the distribution of coal into orderly shape until the effects of the extreme weather had passed and the organization of the Fuel Administration had progressed to the point of enabling it to assume full control. Much of the criticism that has been leveled at the Fuel Administration is based on the happenings of the winter of 1917–18, when no hand could stay the fury of the elements and when sufficient time had not elapsed from the inception of Government control to furnish an adequate organization to handle the situation.

Contrasted with the uncertainty and disturbance in 1917 and the first months of 1918 was the definiteness of purpose and of control that existed once the Fuel Administration had become organized and its policies had become formulated and were appreciated by the industry and the public. The definite and positive control of distribution by the Fuel Administration began on April 1, 1918, with the installation of the zone system and the allotment of coal under the budget system. By the 1st of July it was apparent to those closely in touch with conditions that, barring unforeseen contingencies, the country would be fueled for the year, and by the 1st of October there was no doubt as to the outcome. In fact by October the problem in certain areas was not to find coal to meet the demand, but to find consumers to take the coal that was being produced. After the signing of the armistice, November 11, the demand for coal appreciably slackened, because of the cessation of war industry, and by the end of the year the lack of market was an important

factor with many bituminous coal districts and mines operating on part time.

There was no coal shortage in 1918; sufficient coal, both anthracite and bituminous, was produced to care fully for all needs, and there can be no doubt that, even had the war continued, the country would not have suffered from lack of fuel. The mildness of the winter of 1918–19 of course entailed a decrease in the requirements, particularly of anthracite for house use.

In six months of the year, from May to October, the production of bituminous coal exceeded 50,000,000 tons a month, and in July and August it exceeded 55,000,000 tons. These figures indicate the present possibility of a production of 600,000,000 tons a year. If the year is viewed as a whole, it is evident that the only factor limiting the production of bituminous coal was lack of demand—that is, in 1918 all the coal required by consumers was produced, and a greater quantity could and would have been produced had the demand continued in October, November, and December as strong as it was in the first eight months of the year. The production of bituminous coal increased faster than the consumption, and this, it may be stated, is the only sure way to prevent a coal shortage. When the margin between supply and demand is small consumers are inclined to overstate their requirements through fear of actual shortage, and a condition of panic is thus induced. It is safe to say that even had the war continued through the winter of 1918–19, the supply of coal in the hands of consumers and the facilities for production and distribution were such that the market for coal would have declined and prices here and there would have dropped below the Government maxima.

That a greater output was not reached month by month in the first eight months of the year when the demand was at its height, was due to car shortage. In the first five months of the year lack of cars was a large cause of nonproduction, but from June on the supply of cars was increased and, except for a brief period in August, car shortage was relatively of little more importance than the other causes affecting output. The accompanying diagram (fig. 69) shows the percentage of full-time operation and of losses by causes. This diagram should be considered in conjunction with figure 72 (p. 703), which shows production by weeks in 1918.

Consumption of bituminous coal in 1918 was notably increased by the establishment or enlargement of several large war-munition plants, such as the smokeless-powder plant at Nashville, Tenn., the powder plant at Hopewell, Va., and the Muscle Shoals nitrate plant in Alabama. The use of electric power by the shipyards and other establishments working on war contracts put excessive loads on many central power stations along the Atlantic seaboard and required the consumption of additional quantities of steam coal. Offsetting these increased industrial requirements were the efforts to conserve coal by improved practice in utilization, efforts that in some States, as Massachusetts, resulted in appreciable saving.

Unusually large stocks of bituminous coal were accumulated throughout the country in the summer and fall of 1918. The Fuel Administration adopted the definite policy of urging early and abundant storage of coal and controlled the distribution of stocks only in order to assure to all, in their order of importance, a fairly equal share of such future supplies. The consumers farthest from the mines, as

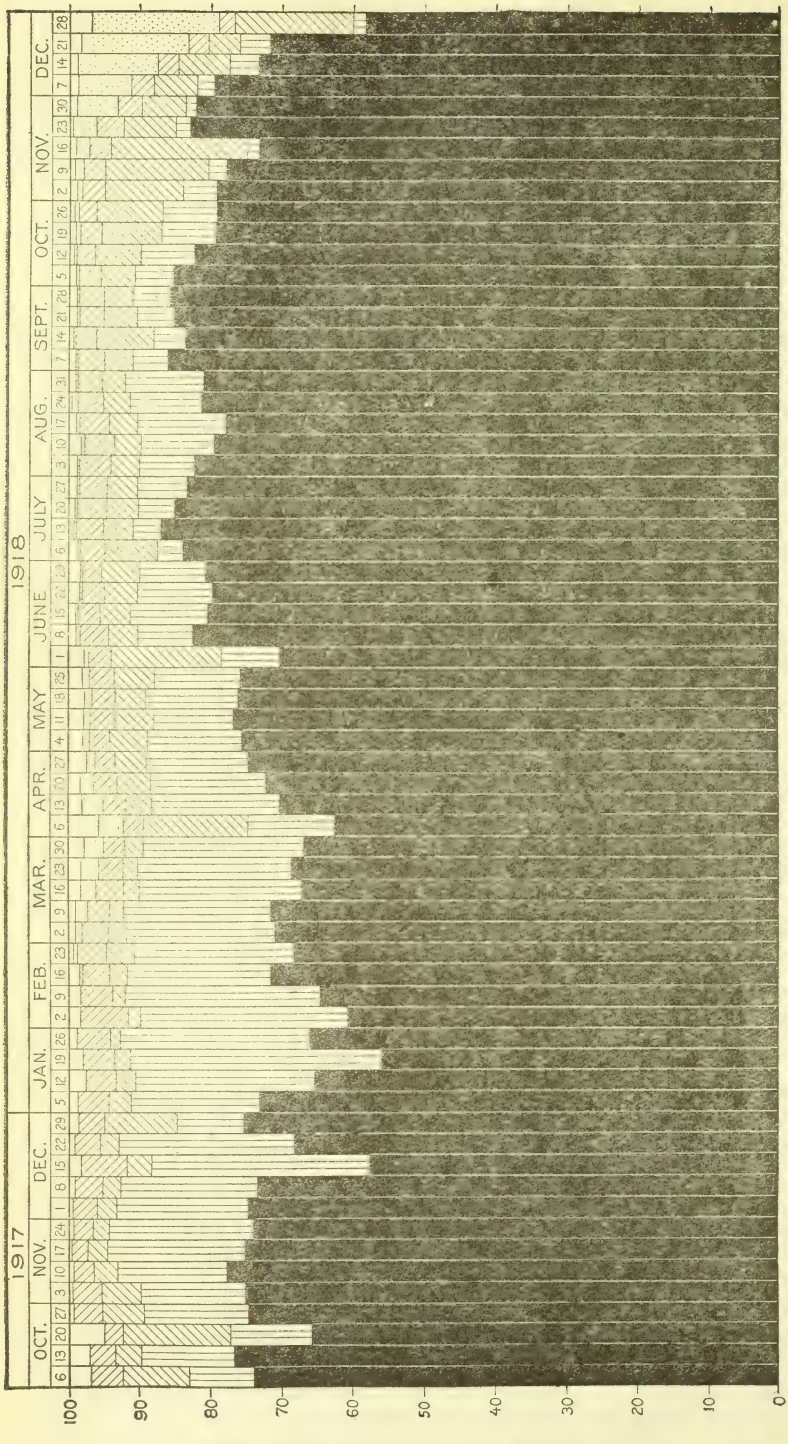

FIGURE 69.—Percentage of full-time operation of all bituminous coal mines in the United States and of losses, by causes and weeks, from October, 1917, to December, 1918.

in New England, the Northwest, Michigan, and on the southeastern Atlantic seaboard, were provided earlier and with larger supplies than the consumers nearer the mines. Thus in parts of New England stocks sufficient for 15 weeks were accumulated by early fall, compared with stocks for 3 to 6 weeks in Ohio.

Prices of coal were regulated throughout the year by the Fuel Administration. The subject of prices has been discussed in a separate report,[1] to which the reader is referred.

The supply of labor for the mining of bituminous coal was ample in 1918, but scarcity of men restricted the output of Pennsylvania anthracite. Although the total number of men employed in the production of bituminous coal was greater in 1918 than in 1916 or in 1917, the increase was in the number of surface employees and not in those at work underground. On pages 711-724 of this report the statistics of labor are reviewed in detail. Strikes were almost unknown in 1918, the record in this respect being the best covered by the available statistics.

For a more intimate and detailed survey of the history of the coal industry in 1918 the reader is referred to the report of the distribution division of the Fuel Administration already mentioned. The report of the engineers' committee of the Fuel Administration contains diagrams of costs of production of both bituminous coal and anthracite as compiled for use in fixing prices. The section on the Fuel Administration in the report by the War Industries Board on government control of prices gives additional data on the industry in 1918.

PRODUCTION.

Summary of statistics of coal produced in the United States in 1917 and 1918.

	1917		1918	
	Quantity (net tons).	Value.	Quantity (net tons).	Value.
Bituminous coal and lignite	551,790,563	$1,249,272,837	579,385,820	$1,491,809,940
Pennsylvania anthracite	99,611,811	283,650,723	98,826,084	336,480,347
	651,402,374	1,532,923,560	678,211,904	1,828,290,287

	Increase, 1918.			
	Quantity.		Value.	
	Net tons.	Per cent.	Dollars.	Per cent.
Bituminous coal and lignite	+27,595,257	+5.0	+$242,537,103	+19.4
Pennsylvania anthracite	− 785,727	−0.8	+ 52,829,624	+18.6
	+26,809,530	+4.1	+ 295,366,727	+19.3

The production in 1918 of 579,385,820 net tons of bituminous coal and of 98,826,084 net tons of Pennsylvania anthracite established a new high record for bituminous coal and was second only to 1917 in

[1] Lesher, C. E., Prices of coal and coke, 1913–1918: U. S. Geol. Survey Mineral Resources, 1918, pt. 2, pp. 15–115, 1919.

the output of anthracite. The increase in the production of bituminous coal exceeded that of 1917 by 27,595,257 tons, or 5 per cent. The decrease in output of anthracite was 785,727 net tons, or 0.8 per cent. For bituminous coal 1918 marks the fourth successive year of increase following the depression of 1914, the production in 1918 being 37 per cent greater than in 1914.

New high records of production of bituminous coal were set in 1918 in 15 out of 30 States. In the remaining 15 States the highest re-

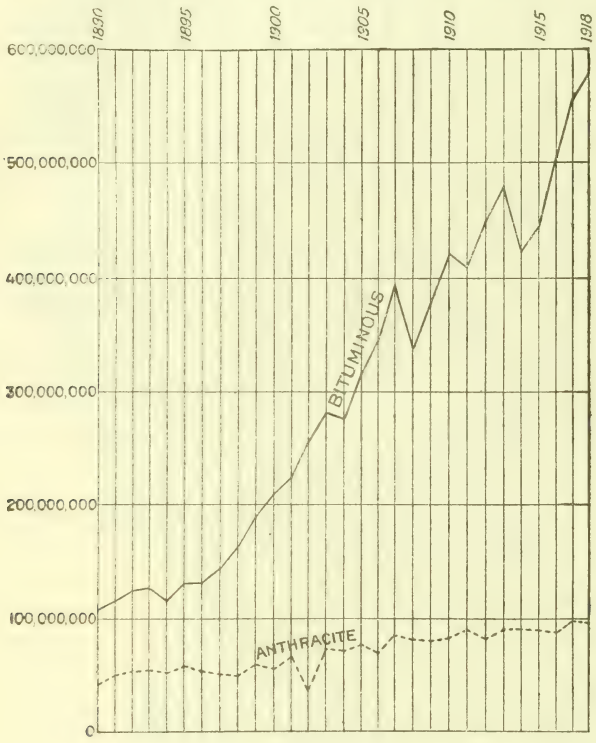

FIGURE 70.—Production of bituminous coal and anthracite in the United States, 1890–1918.

corded production was as follows: In 5 States, Alabama, Colorado, Iowa, Missouri, and North Dakota in 1917, Arkansas in 1907, California in 1880, Georgia in 1903, Maryland and Michigan in 1907, North Carolina in 1899, Oregon in 1904, South Dakota in 1914, Tennessee in 1910, and Texas in 1913. The six leading States in the production of bituminous coal, Pennsylvania, West Virginia, Illinois, Ohio, Kentucky, and Indiana were among those setting new high records in 1918.

Coal produced in the United States in 1918, by States, and highest recorded production, by years.

State.	Quantity.	Maximum production.	
		Year.	Quantity.
	Net tons.		*Net tons.*
Alabama	19,184,962	1917	20,068,074

Pennsylvania (anthracite)	98,826,084	1917	99,611,811

a California only.

The progress of the industry from 1890 to 1918 is shown graphically in figure 70. It will be noted that the development of the anthracite industry has in no way kept pace with that of bituminous coal. In 29 years the production of anthracite slightly more than doubled, but that of bituminous coal increased fivefold. The reason for this discrepancy is found primarily in the limited reserves of anthracite as compared with the almost boundless resources of bituminous coal, but it also lies in the fact that anthracite is essentially a domestic fuel whose production has followed more closely the increase in population, whereas bituminous coal is the fuel of industry and has kept pace with industrial expansion in the country. Furthermore, the yearly variations in the production of anthracite are largely the result of weather conditions; but the yearly variations in the production of bituminous coal follow the curve of industrial expansion and depression.

The production of bituminous coal and lignite in the United States, by months in the six years 1913 to 1918 is given in the following table and is shown graphically in figure 71. The significant feature of this diagram is the seasonal drop in the curve in the years 1913 to 1916, and the practical reversal of this drop by a rise in the middle of 1918.

Bituminous and anthracite coal produced in the United States, 1913–1918, by months, in net tons.[a]

[a] Monthly production estimated for bituminous coal on basis of rail shipments; for anthracite, on basis of monthly reports of Anthracite Bureau of Information.

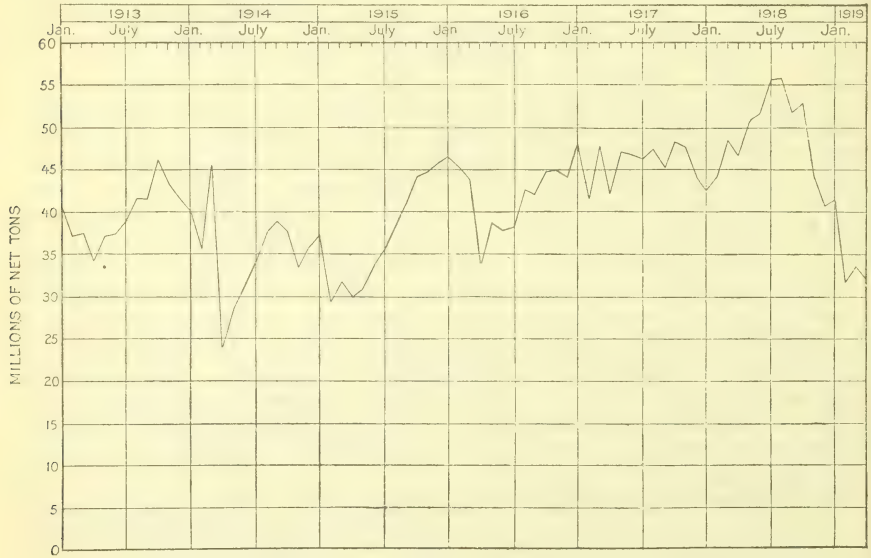

FIGURE 71.—Production of bituminous coal in the United States by months, 1913–1918.

The production of bituminous coal and anthracite in 1918, by weeks, is shown graphically in figures 4 and 5. The comparison of production by weeks shows even more clearly the fluctuation in the rate of production than the comparison by months, which is affected by the difference in the number of working days in the months.

Bituminous coal and lignite produced in the United States in 1918, by weeks, in net tons.

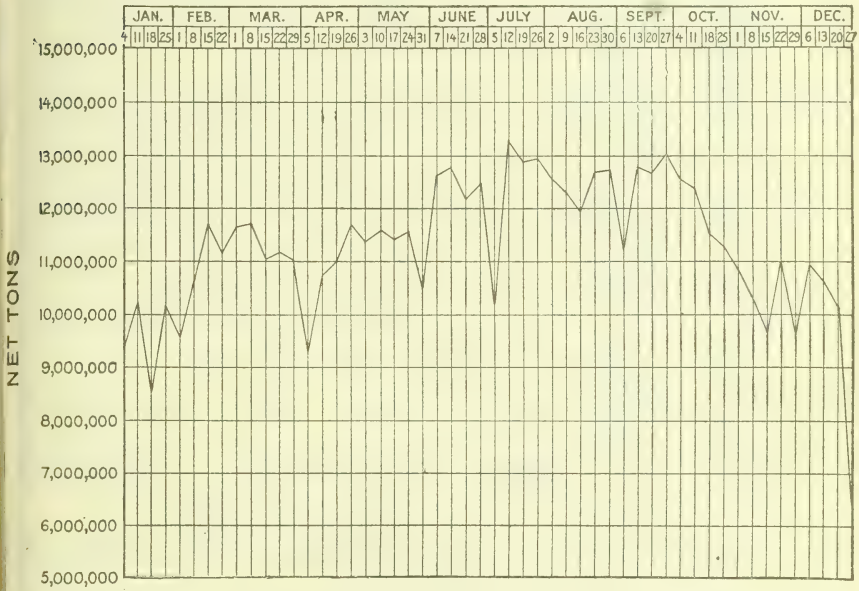

FIGURE 72.—Production of bituminous coal in the United States by weeks, 1918.

The increase in production in 1918 compared with 1917 was not shared equally by all producing fields. Among the more important producing States, Indiana, Kentucky, Ohio, Tennessee, Utah, and Wyoming each recorded gains of more than 10 per cent, whereas Alabama, Colorado, Iowa, Maryland and Texas had decreased output. The significant feature of the statistics of production for 1918 is that the eastern bituminous coal fields, in Pennsylvania, West Virginia, and Virginia, had a substantial increase in 1918 over 1917 as against the small increase in 1917 over 1916. In 1917 the largest gains were made in the middle western territory in fields not tributary to the critical eastern consuming markets, and for that reason the lack of coal in the northeastern United States was acute in 1917 and the early months of 1918.

The increase in 1918 over 1917 in eastern Kentucky, Ohio, and Michigan, the markets for which lie mainly to the west and northwest of the mines, was 14 per cent, compared with 11.6 per cent in 1917 over 1916. In the southern fields Tennessee recorded a gain in 1918 of 10.3 per cent over 1917, as against only 0.9 per cent in 1917, whereas Alabama had a decrease of 4.4 per cent in 1918 and an increase in 1917 of 11 per cent.

The middle western fields, in Illinois, Indiana, and western Kentucky, increased by 6.4 per cent in 1918, compared with 30.7 per cent in 1917. The fields in North Dakota, Iowa, the Southwest, and Texas recorded a decrease of only 0.2 per cent in 1918, as against a gain of 16.2 per cent in 1917 over 1916. In the Rocky Mountain region the gains were 6.4 per cent in 1918 and 13.7 per cent in 1917, and in Washington 1.8 per cent and 32 per cent, respectively.

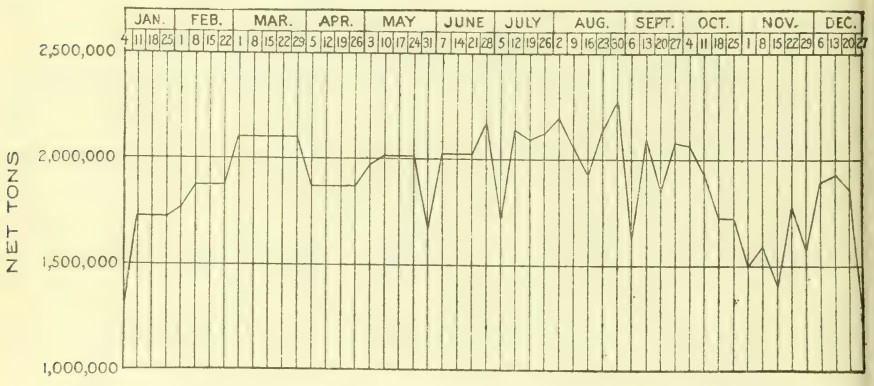

FIGURE 73.—Production of Pennsylvania anthracite, by weeks, 1918.

[a] Does not include production in Alaska, California, Georgia, Idaho, North Carolina, and Oregon.

Comparative statistics of production for 1917 and 1918 by fields are given in the accompanying table. The subdivisions are those adopted by the Fuel Administration for administrative purposes, each field being the unit in which a district representative was placed. These fields do not conform exactly to trade usage; as, for instance, there are six recognized trade districts in Illinois, though the Fuel Administration treated the State as one field.

Bituminous coal produced in 1917 and 1918, by districts.[a]

[a] Does not include production in Alaska, California, Idaho, North Carolina, Oregon, and South Dakota.

The statistics of production by States in 1917 and 1918 are given in the tables on pages 707–708, which are discussed in proper sequence later in the report. In the first column of the tables the quantities loaded at the mines on railroad cars or on boats for shipment are given. Some of the coal reported under this heading, however, is shipped only a short distance and is really used locally. For instance, a considerable portion of the coal mined in the Birmingham, Ala., district is used locally by the iron and steel industry, but as the coal is loaded on railroad cars and as the tonnage appears in the statistics of movement of coal it is placed under the heading of shipped coal. A portion of the coal made into beehive coke in the mining regions is loaded on cars, and, although transported perhaps only a mile or less, is recorded as shipped coal. It should be noted that not all the coal shipped carries a freight charge or furnishes revenue for

the railroads, as the coal for the use of the roads that enter the coal fields is nonrevenue freight.

In the second column the quantities used locally are given. Under that designation are included wagon trade, coal used by employees, coal loaded directly from the tipple into engine tenders, and that part of the product used in the immediate vicinity of the mine by such industries as brick and sewer pipe plants, power plants, and mills of various kinds. It is presumably transported from the mine to the place of consumption in the mine cars, by wagons or on private tramroads.

The coal used to generate steam and heat for the operation of the mine is shown in the third column, and that charged into coke ovens directly is given in the fourth column.

The total quantity, which is the sum of these items, represents only the usable fuel. Refuse, slate, and bone brought out of the mine or picked or sorted from the coal in the tipple and refuse from washeries and dry-cleaning plants are not considered as part of the quantity of coal produced, although the cost per ton of bringing this material to the surface is as great as that of the coal. The total value is the sum of all the values reported by the individual operators, and the average value is the total divided by the total tons.

The schedules sent out by the Geological Survey request that the total number of full days each mine was operated be given, and also the average number of employees, exclusive of office force and coke workers. The number of days a mine was operated is shown directly by the mine records, and the average number of employees is obtained by dividing the number of days into the total shifts, or "men-days," recorded in the pay rolls or time books at each operation. (See pp. 711–712.) The sum of the number of men thus reported (obtained by the Geological Survey) is considered the total for each county and State, or for the United States, as the case may be. The sum of the men-days for all mines is divided by the total number of days on which the total number of men were at work or that the mines were active.

The quantity and value of the coal produced in each State in the five years 1914–1918 and the change and percentage of change in 1918 are shown in the third of the following tables. The annual production of coal in each State from the time of earliest recorded output until the end of 1918 is given in the tabular statement in the pocket.

State.	Loaded at mines for shipment (net tons).	Sold to local trade and used by employees (net tons).	Used at mines for steam and heat (net tons).	Made into coke at mines (net tons).	Total quantity (net tons).	Total value.	Average value per ton.	Number of employees.			Average number of days worked.

LABOR STATISTICS.

Labor is one of the four factors that are essential in order to provide a supply of coal sufficient for the country's needs, the other factors being reserves, developed mines, and transportation; and labor is one of the four factors that may limit the production of coal, the other three being transportation disability, mine disability, and lack of market.

The United States went through the war and produced coal in quantities never before attained, without shortage of mine labor. It is well, however, to examine the statistics of mine labor in order to ascertain the tendency, if any, in the direction of a shortage and to consider the probable effect of such a shortage on future production. The often reiterated statements of individual coal operators that they are experiencing labor shortage and their complaints that labor shortage is reducing output need explanation, in view of the fact that the total number of men employed in the production of coal in 1918 has been exceeded but once, in 1914.

Conditions with respect to supply of labor in the past few years have been different, however, in the anthracite and the bituminous coal regions. The number of men employed in the production of Pennsylvania anthracite has been steadily decreasing since 1914. In 1900 there were 144,206 men reported in the anthracite region, and the number increased steadily to 179,679 men in 1914, but decreased to 147,121 in 1918. A decrease of 18 per cent in number of men in four years certainly indicates a shortage of labor.

In the bituminous coal regions the total number of men reached a maximum in 1918 of 615,000 men, compared with the previous high records of 603,000 in 1917 and 583,500 in 1914. In the face of these returns there does not appear to have been a shortage of mine labor in 1917 or 1918 in the bituminous regions, at least from a national viewpoint. It remains to inquire to what extent the apparent shortage of labor in the anthracite region affected output and whether there may be any factor in the labor situation in the bituminous regions that is not disclosed in a consideration of the total number of men employed and that has limited or may limit production.

It is well to note first the method by which the Geological Survey obtains the statistics of labor and then to inquire as to the limitations of these statistics. The annual schedules on which operators of coal mines report production and other statistics to the Geological Survey ask the following questions as to men employed:

Total number of full days mine (tipple) was in operation during the year. (Parts of days should be reduced to equivalent in full days) ....
Average number of men employed during the year, excluding coke workers and office force:
Underground..... .....
Surface..... .....

The number of days of operation for a given mine is a matter of record and may easily be determined from the mine records. To determine at all accurately the average number of men employed in the year it is necessary to add the number of man-days of labor and divide the total by the number of days the mine worked. The number of man-days is ascertained by adding for each pay period the number of shifts—that is, one man's work for one day—and making a total for the year of all such subtotals. Unless very detailed records are maintained it is necessary to assume that contract laborers—as miners—work a full day each day they enter the mine. The part days of day-pay labor are taken care of by the pay roll, for part days are paid for as such.

In all probability some operators collect the figures for the Geological Survey by adding the totals of men on the pay roll by pay periods. That will inflate the statistics to the extent that the same employee may appear on the pay rolls of two or more operations in the same period—that is, that factor will introduce duplication in proportion to the rapidity of labor turnover. There is nothing in the nature of the returns to indicate the relative accuracy of the original data, nor does a study of the statistics disclose anything to indicate that they are other than relatively accurate and present a true picture of conditions.

The two sets of figures reported for each mine—days and men—are multiplied together, and the sums of the products for each county, State, and the United States are divided by the respective sums of men employed to determine the average days worked. These data have their limitations. They are not accurate in all details, but they are comparable from year to year for each unit of the industry and represent the best figures obtainable under present comditions, both as to records generally available at mine offices and as to the funds allotted to the Geological Survey for their collection.

STATISTICS OF LABOR IN THE ANTHRACITE REGION.

The supply of labor available for the production of Pennsylvania anthracite decreased notably in the period from 1914 to 1918—from 179,679 to 147,121 men, or 18 per cent. Production in that period increased from 90,821,507 to 98,826,084 net tons, or nearly 9 per cent. From 1917 to 1918 the number of men employed decreased by 4.5 per cent, while production decreased but 0.8 per cent.

It is thus made apparent that in the anthracite region, where the number of men has actually decreased in recent years, production, though limited in 1917 and 1918 below the demand, has increased. It should be stated here that in 1917 and 1918 only one factor—labor supply—limited the output of Pennsylvania anthracite, that the demand throughout the two years was in excess of the supply, and that there was no lack of transportation for anthracite.

Production is dependent not only on the number of men employed but on the number of days the men work. The increase in production from 1914 to 1918 with a decreasing supply of labor was made possible by an increase in the number of days of work. In 1914 the 179,679 men worked an average of 245 days; in 1918 the 147,121 men worked an average of 293 days, a gain of 19.5 per cent, which tended to offset the decrease of 18 per cent in the number of men.

That nearly full-time operation of the anthracite mines was attained in 1918 (293 days out of a theoretical year of 304 working days) shows that the practical limit of production with the labor available was reached. Each year the cost in labor increases because of the greater depths and thinner beds of coal that have to be mined, and therefore no increase in production can be had, nor can even the present production be maintained without a substantial increase over the number of men available in 1917 and 1918.

STATISTICS OF LABOR IN THE BITUMINOUS COAL REGIONS.

The total number of men employed in the production of bituminous coal reached the large total of 615,000 in 1918, exceeding all previous records. With this number of men working an average of 249 days, the unprecedented total of nearly 580,000,000 tons of bituminous coal was produced. Had there been need for a greater quantity of bituminous coal, and had the railroads been able to furnish transportation in excess of what was supplied, those 615,000 men could have worked more days, for there are 304 possible working days in a year. From the national standpoint, therefore, it is plain that no shortage of labor existed in the bituminous coal regions in 1918.

There were complaints of labor shortage in 1918 from several districts and from many mines. Such complaints of labor shortage are made regularly and currently from all fields and indicate a situation that is separate and distinct from labor shortage as considered from the national viewpoint. Before attempting to define labor shortage it is necessary to explain the intimate relation between car supply and labor supply, for in that relation is found the reason for common and current declarations of labor shortage by operators of coal mines.

Four causes of the nonoperation of a coal mine are recognized—lack of transportation to carry the coal to market, lack of labor to operate the mine, physical disability in or about the mine preventing

its operation, and lack of market for the coal. Except in periods of general strikes, as in Ohio and Colorado in 1914, lack of men to operate mines is a small factor, for, although the number of men may be less than is desired by any particular operator or group of operators, sufficient numbers of men to justify operation are usually available. Mine disability is not of large moment as a cause of nonoperation; it ranges from 3 to 4 per cent over long periods of time, and except for such disasters as the Cabin Creek flood in August, 1916, does not generally afflict all mines simultaneously.

The mine operator is in the business of producing and selling coal. Experience has shown that one or the other of two impelling causes operates to prevent his fullest realization of that purpose—lack of market or lack of transportation. Lack of market means that the operator is not able to sell all the coal he can produce and would like to sell. In such periods of no demand mines are idle, some for weeks at a time, others for days each week. The demand for coal produced in Indiana in 1916, for instance, was so light that during the summer the mines were idle the greater part of the time and for the year they averaged only 187 days of work.

However, experience has shown that when demand is good and all the producers, or the majority of them have orders for coal that would require the operation of the mines on full time, six days a week, the railroads are not able to meet the demands for cars and transportation—that is, the railroads are not developed and equipped to the point where they can meet the peak of the load. At such times the combined orders of all operators for cars in which to load coal exceed the number of cars that can be supplied daily by the railroads. When such a condition exists the operator can sell all the coal he can produce, usually, in part at least, at an enhanced price. His profits in such times are measured by the number of cars he may be able to have placed at his mines.

When the number of cars ordered by operators for loading coal equals or exceeds the number that from day to day the railroads can furnish, the railroads prorate the available supply among the mines. The basis for this distribution is the relative capacity of the mines to produce and load coal, which is expressed in the "car ratings" established by the railroads. Thus the supply of cars received at each mine at the time when the operator has the greatest desire for the cars depends upon the mine rating.

As just stated, the mine rating is determined by the capacity of the mine to produce and load coal. Anything an operator may do to increase this capacity will therefore increase his rating and thereby insure him a larger share of the cars available on his railroad. For example, if the combined ratings of mines on a railroad division are 100 cars per day, and the number of cars on that division available for placement at the mines for coal loading on a given day is 80, each mine is entitled to 80 per cent of its rating in cars. If there are 10 mines on this division, each rated at 10 cars per day, each mine is entitled to 8 cars from the total of 80. If one operator by adding to his supply of labor can increase the hourly rate of output by, say, 20 per cent, his rating will be increased to 12 cars per day and his share of the total cars available will thereafter be 20 per cent greater than before. As it is generally true that the mines are developed beyond the present labor supply, the desire to obtain more men and increase

output in times of car shortage is logical and warranted. Individual operators can correctly say that they are short of labor. The point that must be clearly understood is that increases in employees in one or many mines will not at such times and under the conditions described increase the total production of coal. In the assumed case just cited, no matter to what extent one or several of the operators might increase the capacity of their mines by adding to this number of men, there would be only the 80 cars to be loaded by the mines on that particular railroad division.

As between coal-producing districts or fields there may be relative shortages of labor. A district such as that about Pittsburgh, Pa., may have at times, as in 1917 and 1918, undergone a material decrease in the number of men employed in the production of coal because of the nearness of other industries able to offer inducements in the way of higher pay or shorter hours. Just as cars are distributed between mines on a division of a railroad in accordance with the mine ratings, so are cars divided between divisions as a whole on a railroad in accordance with the total ratings of mines on the separate divisions. A general increase or decrease in labor supply and consequently in the capacity and rating of a district will therefore in time affect the car supply received by the district. Thus labor supply affects car supply.

On the other hand, car supply affects labor supply. A continued acute shortage of cars in a district means a corresponding loss of production and enforced idleness of labor. Such enforced idleness causes men to leave the field, and as loss of labor reduces capacity the railroad ratings are decreased. A continuous cycle of causes and effects, car shortage reducing labor supply and labor shortage reducing car supply is at work in all periods of good market for coal.

There is another phase of the labor supply that is not disclosed in the preceding discussion. In the following table the number and percentages of inside and outside employees as reported to the Geological Survey for 1916, 1917, and 1918 are shown. In those three years the total number of men employed in the production of bituminous coal increased from 561,000 to 615,000, or about 10 per cent, but the number of men employed inside increased only from 474,000 to 496,000, or 4.6 per cent. In 1916, of the total number of employees, 84.5 per cent were underground, in 1917 82.6 per cent, and in 1918 only 80.7 per cent. The same condition is reflected in the anthracite region of Pennsylvania, where the percentage of inside labor to the total decreased from 73.0 in 1916 to 71.3 in 1917 and to 69.1 in 1918. The explanation of this proportionately greater increase in outside labor (offered to the writer by those familiar with conditions at the mines) is that the years 1917 and 1918 were both periods of successively greater demand; that operators, in their efforts to increase the number of men at their mines and thereby their capacity, car rating, and car supply, added to their forces any and all labor obtainable; and that a large proportion of the new men could not be used underground and were therefore put at work on the surface. With the return of a dull market in the later part of 1918 and the first half of 1919 it was to be expected that a considerable portion of the extra labor represented in these outside employees should be laid off and that the year 1919 should show a relative decrease in the number of laborers of that class at the mines.

Men employed in the coal mines of the United States in 1916, 1917, and 1918.

a Number of men not reported.
b California includes Idaho and Nevada in 1914 and 1915; Idaho in 1916, 1917, and 1918.

The United States Fuel Administration made an investigation of the labor supply at coal mines along somewhat different lines than those covered by the annual statistics of the Geological Survey. The operators of coal mines were requested to furnish data showing the number of men on the pay roll at certain dates, classified as follows:[1]

Underground:
- Miners and loaders.
- Cutters.
- Motor men, pump men, electricians, and others mechanically employed underground.
- All others.

Surface.

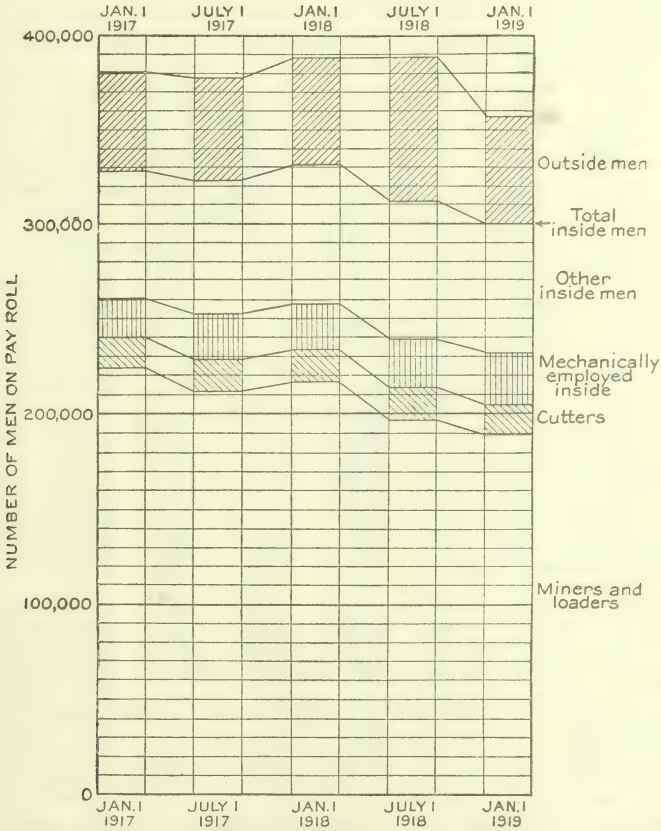

FIGURE 74.—Number of men on the pay rolls of 3,081 bituminous coal mines in the United States at 6-month intervals from January 1, 1917, to January 1, 1919, by classes of labor performed.

The dates covered were January 1, 1917; July 1, 1917; January 1, 1918; July 1, 1918; and January 1, 1919. In tabulating these statistics only such reports were included as were comparable for all the dates given. A number of causes thus prevented the inclusion of all the reports furnished, and the totals therefore do not cover all operations, but they are strictly comparable. These statistics

[1] This classification was made by Mr. S. A. Taylor, of Pittsburgh, Pa., consulting mining engineer of the Fuel Administration.

in detail are contained in Part III of the report of the distribution division of the Fuel Administration. The following table, which is based on these statistics, shows the percentages of labor by the classification noted. Miners, loaders, and cutters, the men actually getting out the coal, represent about 60 per cent of the total labor in the bituminous coal mines and only about 45 per cent of the labor in the anthracite mines. The percentage of surface or outside men at bituminous coal mines reported in these statistics, 14.6 per cent of the total, is below that reported in the annual statistics of the Geological Survey—17.4 per cent in 1917 and 19.3 per cent in 1918—but the percentage reported for the anthracite mines, 31.3 per cent, is higher than that reported to the Geological Survey—28.7 per cent in 1917 and 30.9 per cent in 1918.

Percentages of men employed in the production of coal, by kinds of work, 1917–18.

The diagram (fig. 74) shows graphically the changes by 6-month intervals in the number of men employed in the production of bituminous coal as reported by the operators of 3,081 mines, employing about 60 per cent of the total labor engaged.

Throughout the war the total supply of labor was maintained, the number on the pay rolls at these 3,081 mines in 1918 exceeding the number in 1917. It is significant, however, that the number of miners, loaders, and cutters, the employees that actually produce the coal, decreased in the 2-year period covered by these statistics. The comparative record for January, 1919, showing sharp decreases, can not be held to be of special significance, because at that time

the bituminous trade was passing through a period of unusual winter inactivity. One of the first effects of this slump in business, it is apparent, was the release of extra outside or surface men.

It is evident that the combined effects of the recruiting of mine laborers by other industries and by the Army, either by voluntary enlistment or through the draft, took from the mines the younger and more energetic men, those most active in the production of coal. A continuation of this tendency of decrease in underground workers would in time seriously impair the capacity of the bituminous industry. It can not be said to have done so yet, however, What the course of future events may bring about in the supply of mine labor, through greater emigration of our miners to their home countries abroad and through lack of the acquisition of new hands by immigra-

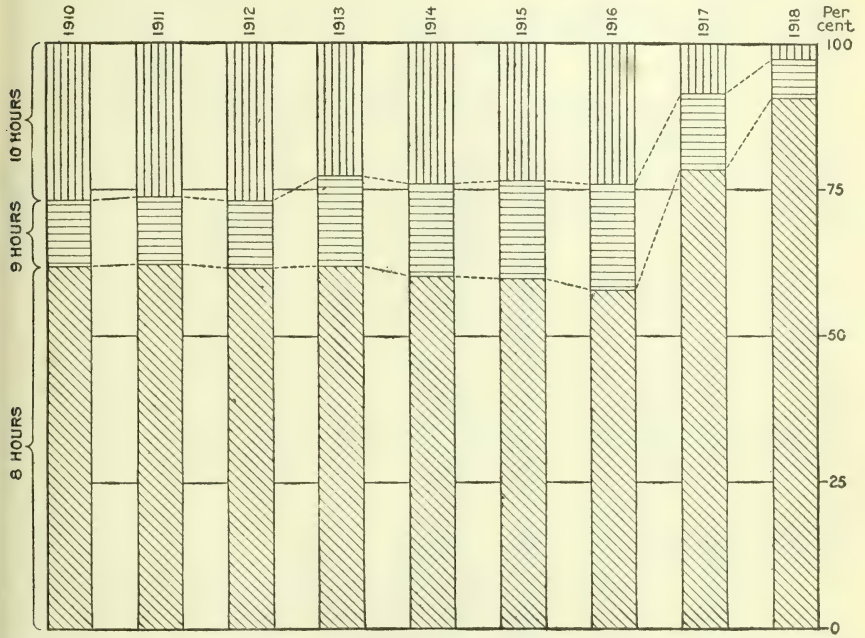

FIGURE 75.—Percentage of labor in bituminous coal mines with established working days of 8, 9, and 10 hours, 1910–1918.

tion, together with losses by desertion to other industries that offer opportunities for more continuous employment than are offered in normal years by the bituminous coal industry, is a present field for speculation.

Further progress in the adoption of the 8-hour working day in the bituminous coal mines was made in 1918. According to the reports made to the Geological Survey, the percentage of men employed in mines where the established working day is 8 hours increased from 79 in 1917 to nearly 91 in 1918, compared with 60 in 1916. The change from 1917 to 1918 was brought about by the more general adoption of the 8-hour day in Alabama, Pennsylvania, Tennessee, Virginia, and West Virginia.

It should be remembered, however, that when the length of the working day is stated reference is made to the number of hours the

mines are supposed to be in operation and not the number of hours the miners actually work. In both the anthracite and the bituminous fields practically all the coal is mined by contract at an agreed rate per ton or other basis of payment. The miner is an independent contractor and is not obliged to put in a certain number of hours at his working place. The figures in the following table really indicate the number of hours the men were given an opportunity to labor during a full working day and do not mean that all the employees worked 8, 9, or 10 hours, as the case may have been.

From 1903, after the settlement of the anthracite strike, until 1916 the established working day in the Pennsylvania anthracite region was 9 hours. Since 1916 the 8-hour day has prevailed in that region.

[a] Includes 346 outside men with 9-hour working day.

STRIKES.

The year 1918 presents a most notable record with respect to strikes and labor trouble in the coal-mining industry. The records of the Geological Survey covering the subject of time lost through strikes in coal mines extend back to 1899, and in no year have these records shown fewer strikes and less time lost on that account than in 1918. The reports for 1918 show 438,882 man-days lost in the bituminous mines because of strikes in 1918—60,105 men for an average of 7 days each. The nearest approach to that figure was in 1907, when 462,392 man-days were lost, but if the time lost is considered together with the total number of men employed or the total man-days worked in the two years, the absence of strikes in 1918 becomes all the more evident.

Labor, of course, laid aside personal contentions during the war. The Government, through the Fuel Administrator, was a powerful influence to anticipate and adjust grievances. The record for 1918 is one of which labor can justly be proud.

No strikes were reported in 1918 from New Mexico and Oregon, where strikes occurred in 1917. A small loss of time on that account was reported from Georgia in 1918, but none in 1917. Among the other States in which strikes were reported in 1917, some decrease in time lost through that cause was recorded in 1918 for all except Michigan, Texas, Virginia, and Washington.

a Bituminous mines only.

PRODUCTION CLASSIFIED BY MINING METHODS.

The term "mining method" as used here refers to the manner in which the coal is broken down in the mine and not to the system of mining, as by room and pillar or long wall. In the mine the coal is either blasted from a solid face—shot from the solid—as in hard-rock mining, or is shot loose or otherwise broken down after a preliminary cut into the coal has been made. This cut may be made by hand or by machine. Underground methods are therefore classified as shooting from the solid, mining by hand, and mining by machine. An increasing quantity of coal is being recovered each year by stripping the cover from the bed in open pits by steam shovels. The bed thus exposed is for the most part shattered by powder and the coal is shoveled into cars by hand, although in places it is picked up directly by small steam shovels.

Opposition to shooting from the solid has arisen because it is injurious to the mining property in that the heavy charges of powder weaken the roof and pillars, thus increasing the liability to falls of roof and coal, the most prolific cause of fatal accidents to coal miners. Another objection to this method is that the heavy charges of powder required to blow down the coal where it has not been previously undercut or sheared result in the production of a much higher proportion of fine coal and render the lump coal so friable that it disintegrates in handling and in transportation. With the growing use of mechanical stokers and of powdered coal the latter objection is losing much of its force, but the danger has been in no wise diminished, and the method is forbidden by law in some of the coal-mining States.

It is interesting to note that in 1918, the year of maximum production, the percentage of product obtained by the use of machines was maintained and even slightly exceeded that in 1917. In 1918 the percentage of machine-mined product was 55.9, compared with 55.5 in 1917. Several of the banner States in the use of machines, however, recorded decreases—particularly Kentucky, from 83.6

per cent in 1917 to 78.5 in 1918; Michigan, from 87.3 to 86.8 per cent; and Ohio, from 87.9 to 84.8 per cent.

The unusually large portion of the total production—more than 8,000,000 tons, or 1.4 per cent—for which the method of mining was not reported in 1918, came largely from small operations, mainly wagon mines, and was probably for the most part shot from the solid. The quantity of bituminous coal mined from steam-shovel pits in 1918 was 8,288,245 tons, or 1.4 per cent of the total output, compared with 5,789,977 tons, or 1.1 per cent of the output in 1917. Bituminous coal was mined from steam-shovel pits in 15 States in 1918, compared with 13 States in 1917, Iowa and Arkansas having been added to the list in 1918.

Bituminous coal mined by different methods in 1917.

PRODUCTION BY MACHINES.

The production of bituminous coal by machines in 1918 was 323,931,000 tons, or 55.9 per cent of the total output, compared with 306,396,000 tons, or 55.5 per cent, in 1917. The number of machines in use increased from 17,235 in 1917 to 18,463 in 1918. The number of machines in use increased in every State except Tennessee, where the number decreased from 209 in 1917 to 200 in 1918, and in North Dakota and Texas, where there was no change. The number of mining machines in use in 1918 was the highest recorded; the previous high record having been reached in 1917. The average output per machine in 1918 was 17,545 tons which has been exceeded only in 1917—17,777 tons per machine.

The quantity of Pennsylvania anthracite mined by machines increased from 1,955,223 net tons in 1917 to 1,857,514 tons in 1918.

Bituminous coal mined by machines in the United States, 1917 and 1918.

Anthracite (Pennsylvania) mined by machines, 1913–1918.

Year.	Quantity (gross tons).	Year.	Quantity (gross tons).
1913	496,229	1916	1,642,416
1914	818,389	1917	1,745,735
1915	1,167,639	1918	1,658,495

PRODUCTION FROM STEAM-SHOVEL PITS.

The steam-shovel branch of the bituminous-coal industry received a marked impetus in 1918 because of the tremendous demand for coal. The number of shovels (the figures here given include electric as well as steam shovels) in use increased from 111 in 8 States in 1916 and 182 in 13 States in 1917 to 276 in 15 States in 1918. The quantity of bituminous coal and lignite recovered from shovel pits rose from 3,933,000 tons in 1916 and 5,790,000 tons in 1917 to 8,288,000 tons in 1918.

The number of steam shovels reported in use in the Pennsylvania anthracite regions increased from 76 in 1917 to 82 in 1918; in both years, however, this was less than the number (105) in 1916.

Coal recovered from steam-shovel strip pits in 1917 and 1918.

COAL-WASHING OPERATIONS.

The quantity of coal washed in 1918 was 25,119,548 tons, from which 22,017,293 tons of cleaned coal was obtained, and more than 3,000,000 tons of refuse thrown out. Compared with both 1917 (25,483,696 tons of cleaned coal) and 1916 (22,922,218 tons of cleaned coal), the record for 1918 represents a decrease. The largest decreases were in Alabama, nearly 2,000,000 tons, and in Pennsylvania, about 1,600,000 tons.

Bituminous coal washed at the mines in 1917 and 1918.

State.	Coal washed (net tons).	Cleaned coal (net tons).	Refuse (net tons).	Percentage of cleaned coal to total State output.

VALUE.

The value of coal given in this report is the realization value at the mine f. o. b. cars, and the average value per ton is the average realization price obtained by dividing the total value by the number of tons sold or produced. The coal used at the mine, the coal coked by the producing company, and the coal used in some other industry by the company operating the mine—an appreciable proportion of the whole—is never sold, and the value placed upon it is either an estimate or the figure at which it is carried on the books, either of which is supposedly based on what the coal would have brought if sold or what other fuel for the respective purpose would have cost if its purchase had been necessary. In other words, the values given represent returns to the operators for coal sold, plus estimated exchange value of that not sold. These figures do not necessarily show prices or even an average of the prices of coal at the mine.[1]

[1] For a study of prices and of Government control of prices, see the report on prices of coal and coke in Mineral Resources of the United States, 1918.

The average price realized for bituminous coal in 1918 was the highest ever recorded. The prices received for coal in 1918 were largely determined by the maxima established by the Fuel Administration, only coal under contract entered into prior to August 21, 1917, not being affected by these Government prices. It has been estimated that the average price realized in 1918 if all the coal had been sold at the prevailing Government price would have been $2.56 a ton compared with the average actually received, $2.58.

The average price realized for anthracite in 1918—$3.40 per net ton—was 55 cents greater than in 1917. The increase in wages paid to miners in 1918 over those paid in 1917 and previous years was largely responsible for the increase in prices, because it increased the cost of production.

Average value per net ton of coal at the mines since 1908.

[a] Value of coal made into coke at the mines included in loaded at mines for shipment.

PRODUCTION OF COAL, BY STATES.

ALABAMA.

The production of coal in Alabama in 1918 was 19,184,962 tons, valued at $54,752,329, a decrease, compared with 1917, of 883,112 tons, or 4.4 per cent, in quantity but a gain of $9,135,337, or 20 per cent, in value. No lack of demand interfered with production of coal in Alabama in 1918 nor was there at any time a serious lack of transportation for the coal from mine to market. The greater part of the coal produced in the State is consumed within a comparatively short distance from the mines and car shortage does not affect this field as in other parts of the country. The decrease in 1918 is to be attributed to an actual shortage of mine labor. There were employed in the production of coal in Alabama in 1918, 26,221 men, compared

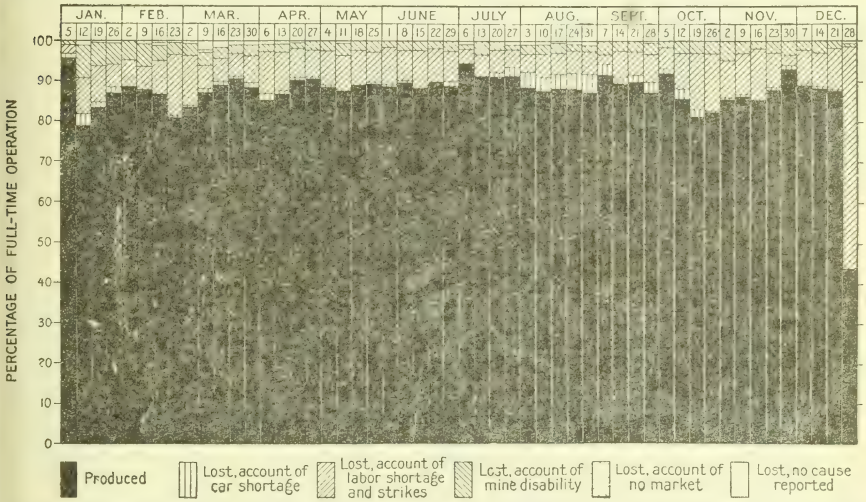

FIGURE 76.—Percentage of full-time operation of coal mines and of losses of running time, by causes and by weeks, in Alabama, in 1918.

with 28,386 men in 1917, a decrease of 8 per cent. Although the working day was in February, 1918, reduced from 9 and 10 hours to 8 hours, there appears to have been no serious curtailment as a result. The average output per man per day in 1918 was 2.63 tons, a slight gain over the record of 2.59 tons in 1917. The average number of days worked increased slightly, from 273 in 1917 to 278 in 1918, and the annual output per employee increased from 707 tons to 732 tons. The decrease in number of men employed was almost entirely among those working underground.

The largest decrease in production was in Jefferson County, the largest producing county in the State. Walker County, the second in importance, had an increase, as did Blount and Winston counties.

The average value per ton was $2.85 in 1918, as compared with $2.27 in 1917, and with a calculated average on the basis of the Fuel Administration prices of $2.67. The actual average return of $2.85 per ton compares with the estimated average price of the Fuel Administration of $2.83 in the last quarter of the year.

Reports of production and of working time made weekly by the operators to the Geological Survey and the Fuel Administration recorded the percentage of full-time operation and the percentages of losses by causes. These data are shown graphically in the accompanying diagram (fig. 76). According to this record the operators in Alabama enjoyed in 1918 more nearly continuous operation than in any other district of comparable size in the country.

ALASKA.[1]

The production of coal in Alaska in 1918 was 75,606 tons, valued at $411,850, compared with 53,955 tons, valued at about $265,317, in 1917. This production was by far the largest in the history of coal mining in Alaska, being 40 per cent larger than the output for 1917, which was also greater than that of any previous year. It is believed that a substantial coal-mining industry has at last begun in Alaska. The larger part of the output in 1918 came from the Matanuska field, which produced 63,092 tons. The remainder came from eight or ten small mines in various parts of the Territory. All these mines, except in the Matanuska and Bering River fields and at Port Graham, produced coal for local use under free-use permits.

In the Matanuska field the Eska Creek mines were operated regularly throughout the year by the Alaskan Engineering Commission to supply fuel for railroad and other Government use. At the Chickaloon mine, also operated by the Alaskan Engineering Commission, the work has consisted primarily of exploration and development, and only a small quantity of coal, won incidentally, has been produced. In 1918 for the first time Matanuska coal was shipped beyond Anchorage. Private operations preparatory to mining were continued by two lessees in the Matanuska field and some coal was mined by one of them, but their mines are not yet regularly productive.

The lignite fields of the Cook Inlet-Susitna district rank next to the Matanuska coal fields in point of production for 1918. A considerable quantity of lignite that was mined near Bluff Point was shipped to towns and canneries on Cook Inlet. A lignite mine on Cache Creek, in the Yentna district, was operated during part of the year to supply fuel for a gold dredge. The Little Susitna mine supplied part of the fuel for the town of Anchorage. It is reported that some coal was mined at Port Graham.

In the Nenana field no leases have yet been granted, but two small mines were opened under mining permits and a small quantity of lignite was mined for use in the construction of the railroad.

It is reported that in the Bering River field the railroad has been extended from its temporary terminus on Bering River to the mine of the Alaska Petroleum & Coal Co. in the eastern part of the field and that small shipments of semianthracite coal were made late in the year. A lease was granted in 1918 to another company for a tract of semibituminous coal land in the western part of the field, and it is reported that extensive operations preparatory to mining are being undertaken.

In northern Alaska lignite mined near Unalaklik, on Norton Sound, was shipped to Nome and St. Michael, and lignite mined on Kobuk River was shipped to Kotzebue. It was reported that lignite would be mined on Kugruk River, Seward Peninsula, during the winter of 1918–19 for use at the placer mines on the Inmachuk.

The following tables give the estimated production of coal in Alaska since 1888. The production for 1888 to 1896 is estimated from the best data available but is only approximate. The figures for 1897 to 1918 are based for the most part on data supplied by the operators. Most of the coal mined before 1916 was lignite. There was a small production of bituminous coal from the west end of the Bering

[1] Martin, G. C., The Alaskan mining industry in 1918: U. S. Geol. Survey Bull. 712, pp. 24-26, 1919.

River field in 1906. The table does not include 855 tons of coal mined in the Bering River field in 1912 and 1,100 tons mined in the Matanuska field in 1913 for test by the United States Navy.

Coal produced in Alaska, 1888–1918.

ARKANSAS.

Each of the important coal producing counties in Arkansas recorded gains in 1918 compared with 1917, the output for the State, 2,227,369 tons, representing an increase over 1917 of 83,790 tons, or 3.9 per cent. The strong demand for high-grade domestic coal in the Western States from which Pennsylvania anthracite was diverted by the Fuel Administration in 1918, resulted in a substantial gain in the output from the

"Arkansas anthracite" mines in Franklin and Johnson counties. The number of days worked increased from 187 in 1917 to 204 in 1918, and the average number of men employed remained about the same—3,978 in 1918 as against 3,998 in 1917.

CALIFORNIA AND IDAHO.

The production of coal, bituminous and lignite, in California and Idaho in 1918 was 6,400 tons, approximately the same as in 1917. The statistics for Idaho are combined with those for California in order not to reveal the operations of the two producers, both small, in Idaho.

Coal produced in California, 1911–1913, in California, Idaho, and Nevada in 1914 and 1915, and in California and Idaho in 1916, 1917, and 1918.

Year.	Loaded at mines for shipment (net tons).	Sold to local trade and used by employees (net tons).	Used at mines for steam and heat (net tons).	Total quantity (net tons).	Total value.	Average value per ton.	Number of employees.	Average number of days worked.

COLORADO.

Colorado, the largest coal-producing State west of Mississippi River and the eighth in rank in the United States, had a production in 1918 of 12,407,571 tons, a slight decrease (75,765 tons, or 0.6 per cent) as compared with 1917. The lignite districts in the northern part of the State (Boulder and Weld counties) increased their output, but the lignite mines in El Paso County had a decrease in production. The production of bituminous coal in the Trinidad field increased, and a decrease of 109,553 tons in Las Animas County was more than offset by an increase of 175,471 tons in Huerfano County. There was practically no change in Fremont County (the Canon City field), but the production in Routt County decreased 132,748 tons, or 12 per cent, largely because of car shortage in the early months of the year. Compared with 1917 when 14,231 men worked an average of 263 days there were in 1918 14,483 men who worked an average of 255 days.

Coal produced in Colorado in 1917.

GEORGIA.

The two companies operating coal mines in Georgia (both of whom have kindly granted permission for the publication of their combined statistics as the State totals) had a production in 1918 of 66,716 tons, compared with 119,028 tons in 1917. The decrease was apparently largely due to lack of men, the total number of employees decreasing by 32 per cent.

Coal produced in Georgia, 1914, 1915, 1916, 1917, and 1918.

Year.	Loaded at mines for shipment (net tons).	Sold to local trade and used by employees (net tons).	Used at mines for steam and heat (net tons).	Made into coke at mines (net tons).	Total quantity (net tons).	Total value.	Average value per ton.	Number of employees.	Average number of days worked.

ILLINOIS.

A new high record for production of coal in Illinois was established in 1918 by an output of 89,291,105 tons, an increase over the previous high record of 1917 of 3,091,718 tons, or 3.6 per cent. By far the greater part of this increase came from the three southern counties, Franklin, Williamson, and Saline, in which is produced the highest-grade coal in Illinois. The central or Springfield district also had an increase, as did the Bellville and Danville districts, but the northern and Fulton-Peoria districts recorded decreases. The proportionately large increase obtained in the southern field was made possible by the

developments in the last few years and because of the need and demand for the excellent coal from this field to fill the requirements of consumers who were denied the higher grades of eastern coal by the zoning system. The following table shows in a general way the relative progress of the principal producing districts in Illinois from 1916 to 1918. As the totals given were arrived at by combining county totals and not all the counties in the State are included and because the fields described are not actually defined by county lines, the following record must be considered as relative rather than as representing the actual production in these well-known trade and rate districts.

Production of coal in Illinois, by groups of principal counties, 1916–1918, in net tons.

Field.	County.	1916	1917	1918
Northern	Grundy, Will, La Salle, Bureau, and Putnam	3,458,000	3,738,000	3,215,000
Danville	Vermilion	2,834,000	3,886,000	3,973,000
Fulton-Peoria	Tazewell, Rock Island, Fulton, and Knox	4,203,000	5,215,000	4,663,000
Central	Logan, Macon, Christian, Montgomery, Menard, Moultrie, Macoupin, and Sangamon.	17,234,000	23,848,000	24,519,000
Belleville	Madison, Bond, St. Clair, Monroe, Randolph, Perry, Marion, and Jefferson.	12,872,000	17,716,000	18,758,000
Southern	Franklin, Williamson, Saline, and Gallatin	21,686,000	27,363,000	29,623,000

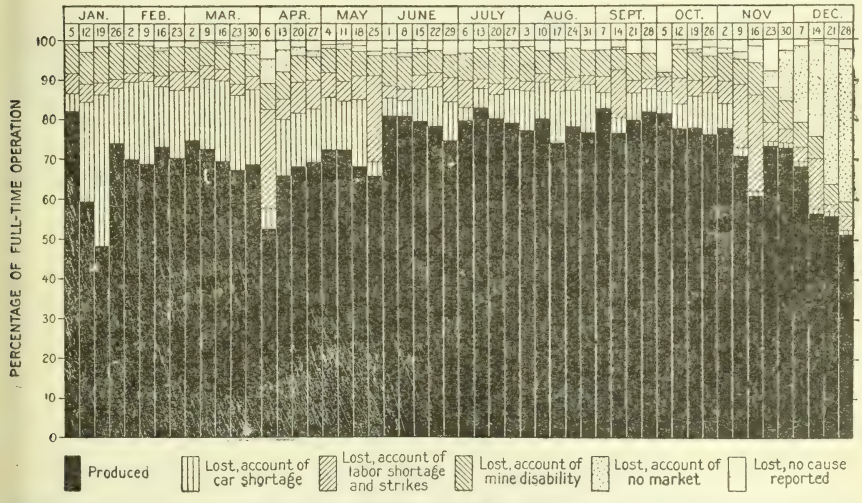

FIGURE 77.—Percentage of full-time operation of coal mines and of losses of running time, by causes and by weeks, in Illinois, in 1918.

The average number of days worked decreased from 243 in 1917 to 238 in 1918 and the number of men increased slightly from 84,090 to 85,965. The average daily output per man, however, increased from 4.22 tons in 1917 to 4.37 tons in 1918, and by reason of the greater effectiveness of the labor the total production for the State was increased. Had not the demand fallen off in the last quarter of the year an even larger production would have been attained.

The weekly statistics of operation, shown graphically in figure 77, indicate that largely because of lack of cars the mines in Illinois aver-

aged only about 70 per cent of full running time in the first five months of 1918, and that from June to the end of October the average was increased to nearly 80 per cent. Because of no market, mainly lack of demand for steam coal, which affected the central and neighboring fields, the production declined in November and December to less than 60 per cent.

Coal produced in Illinois in 1917.

County.	Loaded at mines for shipment (net tons).	Sold to local trade and used by employees (net tons).	Used at mines for steam and heat (net tons).	Total quantity (net tons).	Number of employees.			Average number of days worked.

[a] No production in Jefferson County.
[b] Gallatin includes Johnson County.
[c] Greene includes McDonough, Moultrie, and Stark counties in 1917 and 1918.
[d] No production in Morgan County, 1916 and 1918; in Morgan and Schuyler counties, 1917.
[e] McLean, etc., includes Marshall County, 1915; Marshall and Will counties in 1916; Will County, 1917; Logan and Will counties in 1918.

INDIANA.

Indiana, with a production of 30,678,000 tons of coal in 1918, made a remarkable new high record. It is no mean performance for a field of the magnitude of Indiana to double its production in six years, but Indiana accomplished the feat. The production of coal in Indiana in 1912 was 15,285,718, less than half that of 1918, only six years later. Knox County alone increased from 1,619,000 tons in 1914 to 3,823,000 tons in 1918, and Clay County more than trebled its production in the same period. The largest producing county, Vigo, more than doubled its output in the period from 1913, when 4,237,274 tons were mined, to 1918, when the production was 8,935,000 tons.

The increase in 1918 was largely made possible by the greater number of men employed. The number of employees increased from 26,528 in 1917 to 30,376 in 1918. The average number of days

worked increased slightly from 221 in 1917 to 227 days in 1918. The average daily output per employee decreased from 4.52 tons in 1917 to 4.45 tons in 1918.

The weekly operating statistics shown graphically in figure 78 indicate much the same condition in Indiana as in Illinois, lack of cars as the principal cause of nonproduction in the first half of the year and general improvement in the second half until after the armistice, when production declined because of lack of demand.

FIGURE 78.—Percentage of full-time operation of coal mines and of losses of running time, by causes and by weeks, in Indiana, in 1918.

Coal produced in Indiana in 1917.

[a] Complied by the Indiana Coal Trade Bureau. The figures do not include output of wagon mines.

IOWA.

The decrease in production of coal in Iowa from 8,965,830 tons in 1917 to 8,192,195 tons in 1918 was largely due to lack of demand in the spring months. Had the opportunity been extended for continuous operation the supply of both labor and transportation was sufficient to have made possible a production greater in 1918 than in 1917. The average number of days worked in 1918 was 245, as compared with 251 in 1917. During the period in the spring of 1918, when demand was so slack that mines were closed down for days and weeks, there was an exodus of mining labor, with the result that the total number of men employed in the year decreased from 14,266 in 1917 to 13,328 in 1918. The decrease in men was largely among the miners and others working underground.

Coal produced in Iowa in 1917.

County.	Loaded at mines for shipment (net tons).	Sold to local trade and used by employees (net tons).	Used at mines for steam and heat (net tons).	Total quantity (net tons).	Number of employees.			Average number of days worked.
